ARJA: Automated Repair of Java Programs via Multi-Objective Genetic Programming

Yuan Yuan and Wolfgang Banzhaf

Abstract—Automated program repair is the problem of automatically fixing bugs in programs in order to significantly reduce the debugging costs and improve the software quality. To address this problem, test-suite based repair techniques regard a given test suite as an oracle and modify the input buggy program to make the entire test suite pass. GenProg is well recognized as a prominent repair approach of this kind, which uses genetic programming (GP) to rearrange the statements already extant in the buggy program. However, recent empirical studies show that the performance of GenProg is not fully satisfactory, particularly for Java. In this paper, we propose ARJA, a new GP based repair approach for automated repair of Java programs. To be specific, we present a novel lower-granularity patch representation that properly decouples the search subspaces of likely-buggy locations, operation types and potential fix ingredients, enabling GP to explore the search space more effectively. Based on this new representation, we formulate automated program repair as a multi-objective search problem and use NSGA-II to look for simpler repairs. To reduce the computational effort and search space, we introduce a test filtering procedure that can speed up the fitness evaluation of GP and three types of rules that can be applied to avoid unnecessary manipulations of the code. Moreover, we also propose a type matching strategy that can create new potential fix ingredients by exploiting the syntactic patterns of existing statements. We conduct a large-scale empirical evaluation of ARJA along with its variants on both seeded bugs and real-world bugs in comparison with several state-of-the-art repair approaches. Our results verify the effectiveness and efficiency of the search mechanisms employed in ARJA and also show its superiority over the other approaches. In particular, compared to jGenProg (an implementation of GenProg for Java), an ARJA version fully following the redundancy assumption can generate a test-suite adequate patch for more than twice the number of bugs (from 27 to 59), and a correct patch for nearly four times of the number (from 5 to 18), on 224 real-world bugs considered in Defects4J. Furthermore, ARJA is able to correctly fix several real multi-location bugs that are hard to be repaired by most of the existing repair approaches.

Index Terms—Program repair, patch generation, genetic programming, multi-objective optimization, genetic improvement.

1 Introduction

Automated program repair [1]–[3] aims to automatically fix bugs in software. This research field has recently stirred great interest in the software engineering community since it tries to address a very practical and important problem. Automatic repair techniques generally depend on an oracle which can consist of a test suite [4], pre-post conditions [5] or an abstract behavioral model [6].

Our study focuses on the test-suite based program repair that considers a given test suite as an oracle. The test suite should contain at least one initially failing test case that exposes the bug to be repaired and a number of initially passing test cases that define the expected behavior of the program. In terms of test-suite based repair, a bug is said to be *fixed* or *repaired* if a repair approach generates a patch that makes its whole test suite pass. The patch obtained can be referred to as a *test-suite adequate patch* [7].

GenProg [4], [8], [9] is one of the most well-known repair approaches for test-suite based program repair. This general approach is based on the *redundancy assumption*, which means that the code that can be used to generate a repair (called *fix ingredients*) already exists elsewhere in the buggy program; and it uses genetic programming (GP) [10], [11] to search for potential patches that can fulfill the test suite. Although GenProg has been well recognized as a state-of-the-art repair approach in the literature, it has caused certain academic controversies among some researchers.

First, Qi et al. [12] studied to what extent GenProg can benefit from GP. Their results on GenProg benchmarks [9] indicate that just replacing GP in GenProg with random search can improve both repair effectiveness and efficiency, thereby questioning the necessity and effectiveness of GP in automated program repair. Second, an empirical study conducted in [13] pointed out that the overwhelming majority of patches reported by GenProg are incorrect and are equivalent to a single functionality deletion. Here we do not focus on the potential incorrectness of the patches that is mainly due to the weakness of the test suite rather than the repair approaches [14]. Our major concern is the statement that GenProg usually generates nonsensical patches (e.g., a single deletion), which challenges the expressive power of GP to produce meaningful or semantically complex repairs. Lastly, a recent large-scale experiment [7] showed that an implementation of GenProg for Java (called jGenProg) can find a test-suite adequate patch for only 27 out of 224 real-world Java bugs, and only five of them were identified as correct. Obviously, the performance of GenProg for Java is currently far from satisfactory.

Considering these adverse reports about GenProg, it is necessary to revisit the most salient features of the system that qualify it as a well-established repair system. We

think there are at least two important features. One is that GenProg can scale to large programs, mainly owing to its patch representation [9]. The other is that GenProg can potentially address various types of bugs because the expressive power of GP allows for diverse transformations of code. In particular, GP can change multiple locations of a program simultaneously, so that GenProg is likely to fix multi-location bugs that cannot be handled by most of the other repair approaches. The scalability of GenProg is visible since it has been widely applied to large real-world software [7], [9], making it distinguished from those approaches (e.g., SemFix [15] and SearchRepair [16]) that are largely limited to small programs. However, as mentioned before, the expressive power of GenProg inherited from GP has not been well supported and validated by recent experimental studies in the literature [7], [12], [13]. We think it is very important to shed more light on this issue and then address it, which would make GP really powerful in automated program repair.

Generally, a successful repair system consists of two key elements [13]: 1) a *search space* that contains correct patches; 2) a *search algorithm* that can navigate the search space effectively and efficiently. For the search space, GenProg uses the redundancy assumption, which has been largely validated by two independent empirical studies [17], [18]. This leaves the search algorithm as a bottleneck that might make GenProg unable to fulfill its potential for generating nontrivial patches. The reason could be that the search ability of the underlying GP algorithm in GenProg is not strong enough to really sustain its expressive power.

Given this analysis, our primary goal is to improve the effectiveness of the search via GP for program repair. To this end, we present a new GP based repair system for **a**utomated **r**epair of **Ja**va programs, called ARJA. ARJA is mainly characterized by a novel patch representation for GP, multi-objective search, and several strategies to reduce the search space. Our results indicate that an ARJA version that fully follows the redundancy assumption can generate a test-suite adequate patch for 59 real bugs in four projects of Defects4J [19] as opposed to only 27 reported by jGenProg [7]. By manual analysis, we find that this ARJA version can synthesize a correct patch for at least 18 bugs in Defects4J as opposed to only 5 by jGenProg. To our knowledge, some of the 18 correctly fixed bugs have never been repaired correctly by other repair approaches. Furthermore, ARJA is able to correctly fix several multi-location bugs that are hard to be addressed by most of the existing repair approaches.

The main contributions of this paper are as follows:

1) The solution representation is a key factor that concerns the performance of GP. Inspired by the work of Oliveira et al. [20], we propose a novel patch representation for GP based program repair, which properly decouples the search subspaces of likely-buggy locations, operation types and replacement/insertion code.
2) We propose to formulate automated program repair as a multi-objective optimization problem and employ NSGA-II [21] to search for potential repairs.
3) We introduce three types of rules which are integrated into three different phases of ARJA search (i.e., operation initialization, ingredient screening and solution decoding), in order to reduce the search space effectively.
4) Although our study mainly focuses on improving the search algorithm, we also make an effort to enrich the search space reasonably beyond reusing code already extant in the program. To that end, we propose a type matching strategy which can create promising new code for bug fixing by leveraging syntactic patterns of existing code.
5) We conduct a large-scale experimental study on 18 seeded bugs and 224 real-world bugs, from which some new findings and insights are obtained.
6) We develop a publicly-available program repair library for Java, which currently includes the implementation of our proposed approach (i.e., ARJA) and three previous repair approaches originally designed for C (i.e., GenProg [9], RSRepair [12] and Kali [13]). It is expected that the library can facilitate further replication and research on automated Java software repair.

The remainder of this paper is organized as follows. In Section 2, we provide the background knowledge and motivation for our study. Section 3 describes the proposed repair approach in detail. Section 4 presents the experimental design. Sections 5 and 6 report the experimental results on seeded bugs and real bugs, respectively. Section 7 discusses the threats to validity. Section 8 lists the related work on test-suite based program repair. Finally, Section 9 concludes and outlines directions for future work.

2 Background and Motivation

In this section, we first provide background information of ARJA, including multi-objective genetic programming, the GenProg system and Oliveira et al.'s patch representation. Then, we describe the goal and motivation of our study.

2.1 Multi-Objective Genetic Programming

Genetic programming (GP) is a stochastic search technique which uses an evolutionary algorithm (EA), often derived from a genetic algorithm (GA), to evolve computer programs towards particular functionality or quality goals. In GP, a computer program (i.e., phenotype) is encoded as a genome (i.e., genotype), which can be a syntax tree [10], an instruction sequence [22], or other linear and hierarchical data structures [23]; a fitness function is used to evaluate each genome in terms of how well the corresponding program works on the predefined task. GP starts with a population of genomes that is typically randomly produced and evolves over a series of generations progressively. In each generation, GP first selects a portion of the current population based on fitness, and then performs crossover and mutation operators on those selected to generate new genomes which would form the next population.

Traditionally, the aim of GP is to create a working program *from scratch*, in order to solve a problem encapsulated by a fitness function. Due to the limited size of successful programs that GP can generate, GP research and applications over the past few decades mainly focused on predictive modeling (e.g., medical data classification [24], energy consumption forecasting [25] and scheduling rules design [26]), where a program is usually just a symbolic expression. It was not until recently that GP was used to evolve real-world software systems [4], [9], [27], [28]. Here, instead of

starting from scratch, such GP applications generally take an *existing* program as a starting point, and then improve it by optimizing its functional properties (e.g., by fixing bugs) [4], [9] or non-functional properties (e.g., execution time and memory consumption) [27]–[30]. This paradigm of applying GP is formally called genetic improvement [31] in the literature.

Moreover, most previous usages of GP only consider a single objective. However, there usually exist several competing objectives that need to be optimized simultaneously in a real-world task, which can be formulated as a multi-objective optimization problem (MOP). Mathematically, a general MOP can be stated as

$$\begin{aligned} \min \mathbf{f}(\mathbf{x}) &= (f_1(\mathbf{x}), f_2(\mathbf{x}), \ldots, f_m(\mathbf{x}))^{\mathrm{T}} \\ \text{subject to } \mathbf{x} &\in \Omega \subseteq \mathbb{R}^n \end{aligned} \tag{1}$$

$\mathbf{x}$ is a n-dimensional decision vector in the decision space Ω, and $\mathbf{f} : \Omega \to \Theta \subseteq \mathbb{R}^m$, is an objective vector consisting of m objective functions, which maps the decision space Ω to the attainable objective space Θ. The objectives in Eq.(1) are often in conflict with each other (i.e., the decreasing of one objective may lead to the increasing of another), so there is typically no single solution that optimizes all objectives simultaneously. To solve a MOP, attention is paid to approximating the *Pareto front* (PF) that represents optimal trade-offs between objectives. The concept of a PF is formally defined as follows.[1]

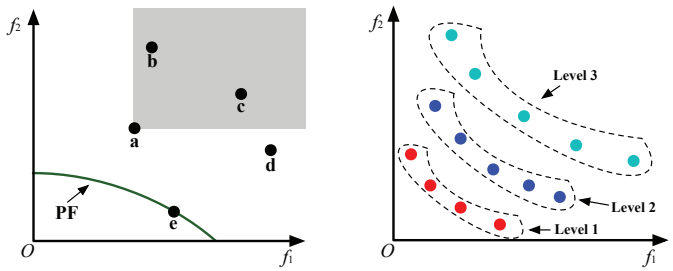
Definition 1 (Pareto Dominance). A vector $\mathbf{p} = (p_1, p_2, \ldots, p_m)^{\mathrm{T}}$ is said to *dominate* another vector $\mathbf{q} = (q_1, q_2, \ldots, q_m)^{\mathrm{T}}$, denoted by $\mathbf{p} \prec \mathbf{q}$, iff $\forall i \in \{1, 2, \ldots, m\} : p_i \leq q_i$ and $\exists j \in \{1, 2, \ldots, m\} : p_j < q_j$.

Definition 2 (Pareto Front). The Pareto front of a MOP is defined as $PF := \{\mathbf{f}(\mathbf{x}^*) \in \Theta \mid \nexists \mathbf{x} \in \Omega, \mathbf{f}(\mathbf{x}) \prec \mathbf{f}(\mathbf{x}^*)\}$.

From Definition 2, the PF is a subset of solutions which are not dominated by any other solution.

Due to the population-based nature of EAs, they are able to approximate the PF of a MOP in a single run by obtaining a set of non-dominated objective vectors, from which a decision maker can select one or more for their specific needs. These EAs are called multi-objective EAs (MOEAs). A comprehensive survey of MOEAs can be be found in [32]. Considering a suitable multi-objective scenario, multi-objective GP evolves a population of candidate programs for multiple goals using a MOEA approach.

Fig. 1(a) illustrates Pareto dominance for a MOP with two objectives. According to Definition 1, all objective vectors within the grey rectangle (e.g., $\mathbf{b}$ and $\mathbf{c}$) are dominated by $\mathbf{a}$, and $\mathbf{a}$ and $\mathbf{d}$ are non-dominated by each other as $\mathbf{a}$ is better for f_1 while $\mathbf{d}$ is better for f_2. Because $\mathbf{e}$ is on the PF, no objective vectors in Θ can dominate it. To provide sufficient selection pressure toward the PF, many Pareto dominance-based MOEAs, e.g., NSGA-II [21], introduce elitism based on non-dominated sorting. Fig. 1(b) illustrates the non-dominated sorting procedure, where the union population (combination of current population and offsprings) is divided into different non-domination levels. The solutions on the first level are obtained by collecting every solution that is not dominated by any other one in the union population. To find the solutions on the j-th ($j \geq 2$) level, the solutions on the previous $j-1$ levels are first removed, and the same procedure is repeated again. The solutions on a lower level will have a higher priority to enter into the next population than those of a higher level.



(a) Pareto dominance (b) Non-dominated sorting

Fig. 1. Illustration of Pareto dominance and non-dominated sorting.

2.2 A Brief Introduction to GenProg

GenProg [4], [9] is a generic approach that uses GP to automatically find repairs of a buggy program. GenProg takes a buggy program as well as a test suite as input and generates one or more test-suite adequate patches for output. The test suite is required to contain initially passing tests to model the expected program functionality and at least one initially failing test to trigger the bug. To obtain a program variant that passes all the given tests, GenProg modifies the buggy program by using a combination of three kinds of statement-level edits (i.e., delete a destination statement, replace a destination statement with another statement, and insert another statement before a destination statement). In the early versions of GenProg [4], [8], [33], each genome in the underlying GP is an abstract syntax tree (AST) of the program combined with a weighted path through it. However, the AST based representation does not scale to large programs, since the memory consumed by a population of program ASTs is usually unaffordable. Le Goues et al. [9] addressed the scalability problem of GenProg by using the *patch representation* [34] instead of the AST representation. Specifically, each genome now is represented as a patch, which is stored as a sequence of edit operations parameterized by AST node numbers (e.g., Replace(7, 13), see Fig. 2(a)). The phenotype of a genome of this representation is a modified program obtained by applying the patch to the buggy input program.

Based on the patch representation, GenProg can use single-point crossover to generate offspring solutions. This crossover randomly chooses a cut point in each of two parents, and the genes beyond the cut points are swapped between the two parents to produce two offspring solutions. Fig. 2(b) illustrates the single-point crossover in GenProg. In crossover, we can only expect material in the two parents to be differently combined, but not newly generated.

The mutation operator is therefore very important in GenProg, because it is responsible for introducing new edit operations into the population. To conduct the mutation on a solution, first each potentially faulty statement is chosen as a destination statement with a probability of mutation rate

[1]In the following we shall assume that the goal is to minimize objectives.

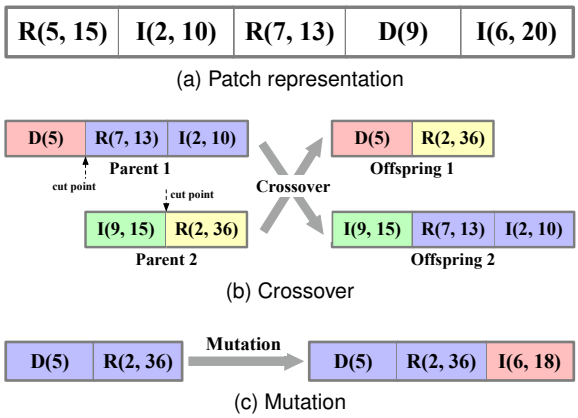

Fig. 2. Illustration of patch representation, crossover, and mutation in GenProg. For brevity, "D" denotes a delete operation; "R" a replace; and "I" an insert. The integers denote the AST node numbers of the corresponding statements. D(a) means that delete "a"; R(a, b) means that replace "a" with "b"; I(a,b) means that insert "b" before "a".

weighted by its suspiciousness. Once a destination statement is determined, an operation type is randomly chosen from three types (i.e., "Delete", "Replace" and "Insert"). In case of "Replace" or "Insert", a second statement (i.e., replacement/insertion code) is randomly chosen from those statements which only reference variables in the *variable scope* at the destination and are visited by at least one test. Each edit operation created in this way is appended to a list of edits in the solution under mutation. Fig. 2(c) illustrates the mutation operator in GenProg.

The overall procedure of GenProg is summarized as follows. First, GenProg localizes potentially buggy statements and gives each of them a weight measuring its suspiciousness. Then, GP searches to obtain an initial population by independently mutating N (the population size) copies of the empty patch. In each generation of GP, GenProg uses tournament selection to select $N/2$ parent solutions for mating from the current population, and conducts crossover (as in Fig. 2(b)) on the parents to generate $N/2$ offspring solutions. Afterwards, it conducts one mutation (as in Fig. 2(c)) on each parent and each offspring. The parents together with the offsprings will form the next population. The GP loop is terminated when a program variant passes all given tests or another termination criterion is reached.

2.3 Oliveira et al.'s Patch Representation

Recently, Oliveira et al. [20] presented a lower-granularity patch representation, which decouples the three subspaces corresponding to three kinds of partial information in an edit operation. Using this representation, the patch represented in Fig. 2(a) can be reformulated as that shown in Fig. 3(a), where the representation is divided into three different parts: the first part is a list of operation types, the second a list of likely-buggy locations, and the third a list of replacement/insertion code.

Based on this representation, Oliveira et al. further suggested three crossover operators. Fig. 3(b) illustrates one of them called OP1SPACE. This crossover first randomly chooses one part in the representation, and conducts single-point crossover only on that part keeping the other two parts unchanged. However, due to different numbers of genes in the three parts after crossover, there exist some invalid genes that should be removed to obtain final offspring solutions. The removal of invalid genes will potentially result in information loss. To relieve this issue, they introduced a memorization scheme to reuse invalid genes.

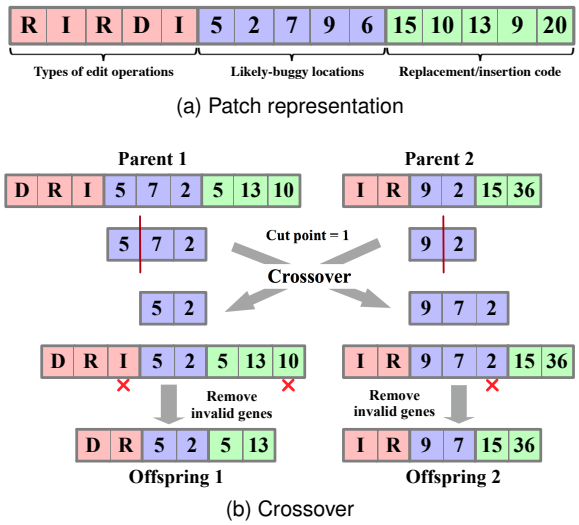

Fig. 3. Illustration of patch representation and crossover introduced by Oliveira et al. [20].

2.4 Goal and Motivation

Our overall goal in this study is to develop a more powerful GP based system for automated repair of Java programs. To this end, we conduct an analysis of the potential limitations of GenProg so as to guide the design of our new system. There are several deficiencies in GenProg that motivated us to pursue this goal, which are discussed as follows.

2.4.1 High-Granularity Patch Representation

In GenProg, each gene in the patch representation (see Fig. 2(a)) is a high-granularity edit operation where the operation type, likely-buggy location (i.e., destination statement), and replacement/insertion code are *invisible* to the crossover (see Fig. 2(b)) and mutation (see Fig. 2(c)) operators. Manipulating such high-level units via GP would hinder the efficient recombination of genetic information between solutions. This is mainly because good partial information of an edit (e.g., a promising operation type, an accurate faulty location, and a useful replacement/insertion code) cannot be propagated from one solution to others. For illustration, suppose there is a bug that requires two edit operations to be repaired: D(5), R(2, 10), and there are two candidate solutions in the population that are the same as "Parent 1" and "Parent 2" in Fig. 2(b) respectively. As can be seen, the two candidate solutions together contain all the material to compose the correct patch. The crossover in GenProg can easily propagate the desired edit D(5) in "Parent 1" to offspring solutions. However, because such crossover does not introduce any new edit, it cannot produce R(2,10), even though I(2, 10) in "Parent 1" and R(2, 36) in "Parent 2" are both one modification away and their desired partial information can be obtained from each other. The mutation in GenProg creates new edits from scratch, where the

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

operation types and replacement/insertion code are just randomly chosen from all those available. Thus, there is only a slim chance for mutation to produce exactly R(2,10).

The representation by Oliveira et al. [20] makes the search explicitly explore three subspaces and thus overcomes GenProg's drawback of over-constraining the search ability to some extent, but it may lead to new problems. One problem is that the invalid genes can lead to the loss of good partial information. The memorization scheme may be helpful, but it does not appear to increase the success rate of repair as indicated in [20]. Another problem is that the crossover on this representation exchanges information of operation types and replacement/insertion code between different likely-buggy locations very frequently. However, this situation may not be desirable because every likely-buggy location has its own syntactic/semantic context, and their preferable operation types and replacement/insertion code can vary a lot. Moreover, due to scoping issues, just the available replacement/insertion code can be quite different at different likely-buggy locations, so exchanging replacement/insertion code between such locations may easily result in an uncompilable program variant.

Our study aims to propose a novel lower-granularity patch representation that can address the limitations of GenProg's representation while avoiding the above two problems caused by the representation introduced in [20].

2.4.2 Limitation With Respect to Multi-Edit Patches

It is common that a bug repair requires multiple edits to the buggy program. For example, among 224 real bugs of four projects (i.e., Chart, Time, Lang and Math) in Defects4J [19], over two third of human-written patches contain at least two statement-level edits. However, most of existing repair approaches are poor at creating multi-edit patches. Some approaches such as SemFix [15] and Nopol [35] even have no ability in this respect since they handle each possibly faulty statement separately. GP based approaches such as GenProg can manipulate multiple faulty statements simultaneously, so they have the potential to find multi-edit patches. However, an empirical study by Qi et al. [13] indicated that most of patches generated by GenProg are indeed equivalent to a single functionality deletion. The recent experimental results [19] on Defects4J also showed that GenProg does not succeed in fixing any bug that may really need multiple edits. To our knowledge, there has been no consensus in the literature on GenProg's weakness in the multi-edit patch generation. We think that the search ability of the underlying GP in GenProg matters a lot.

Our study aims to address the limitation of GenProg with respect to multi-edit patches via a novel multi-objective GP with stronger search ability.

2.4.3 Expensive Fitness Evaluation

In GenProg, all given tests need to be run in order to evaluate the fitness of a solution accurately. However it is usually computationally expensive to run all the associated tests of real-world software. Expensive fitness evaluations will limit the use of a reasonably large number of generations or population size in GP, thereby greatly limiting the potential of GP for program repair. To relieve this problem, Fast et al. [36] proposed to just use a random sample of given tests for each fitness evaluation. That strategy can increase efficiency, but it will unavoidably reduce the precision of the search.

We argue that not all given tests are necessary for fitness evaluation. In fact, many can be omitted to speed up fitness evaluation, but without affecting the precision of search.

2.4.4 Limited Utilization of Existing Code

Today, large Java projects are commonly developed by many programmers, each of whom is responsible for only one or several modules. Although the names of important APIs or even field variables can be determined in the software design phase, the names of local variables and private methods are generally chosen based on the preference of the responsible programmer, which leads to the fact that even variables or methods with similar functions can have different names in different Java files. Thus, for a likely-buggy location, it is sometimes possible that we can make an invalid statement become its hopeful replacement/insertion code by replacing the invisible variables or methods with similar ones in the scope. In other words, the underlying pattern in a statement other than the statement itself can also be exploited to acquire useful replacement/insertion code. GenProg does not create any new code, in which the replacement/insertion code is just taken from somewhere else in the buggy program without change. This practice may fail to make the most of the existing code.

Our study aims to present a strategy that can exploit the pattern of the existing code appropriately, so as to create some new replacement/insertion statements that are potentially useful.

2.4.5 Limited Utilization of Constraints Enforced by the Compiler

GenProg can conduct any deletion, replacement or insertion on the possibly faulty statements, provided that the replacement/insertion code meets the variable scope. However, some operations indeed make little sense from the view of programmers. Two main reasons are given as follows.

One reason is that although a replacement/insertion statement conforms to the scope of variables and methods at a destination, it can still violate other Java specifications when it is pasted to that place. Another reason is that certain operations either disrupt the program too much or have no effect at all. For example, in Fig. 4, if we delete the variable declaration statement (at line 1092), all the remaining statements will be invalidated immediately since they all reference the variable `cloned`. Moreover, even if a variable declaration statement should be deleted, leaving it as a redundant statement generally does not influence the correctness of the program. Thus the deletion operation here is not desired and should be disabled.

```
1092  final StrTokenizer cloned = (StrTokenizer) super.clone();
1093  if (cloned.chars != null) {
1094      cloned.chars = cloned.chars.clone();
1095  }
1096  cloned.reset();
1097  return cloned;
```

Fig. 4. The code snippet excerpted from the Commons Lang project.[2]

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

Our study aims to encode such constraints enforced by the compiler as a number of rules, which can be integrated into the proposed repair method flexibly. We expect that the search space of GP can be reduced effectively with these rules. Note that our aim is very different from that of [37]. The rules considered in our study disallow definitely unnecessary operations rather than likely unpromising ones, so they generally do not restrict the expressive power of GP.

3 Approach

This section presents our generic approach to automatically finding the test-suite adequate patches via multi-objective GP. This approach is implemented as a tool called ARJA that repairs Java code.

3.1 Overview

In a nutshell, ARJA works as depicted in Fig. 5. ARJA takes a buggy program and a set of associated JUnit tests as the input. Among the tests, at least one *negative* (i.e., initially failing) test is required to be included, which exposes the bug to be fixed. All the remaining are *positive* (i.e., initially passing) tests, which describe the expected program behavior. The basic goal of ARJA is to modify the program so that all tests pass. Its process contains the following main steps.

Given the input, a fault localization technique is used to identify potentially buggy statements which are to be manipulated by GP. Meanwhile, coverage analysis is conducted to record every statement that is visited by any JUnit test. These statements collected in the coverage analysis (referred to as *seed statements* in ARJA) provide the source of the replacement/insertion code (referred to as *ingredient statements* in ARJA). Note that fault localization and coverage analysis both require the Eclipse AST parser to transform the line information of code to the corresponding Java statements.

Once the likely-buggy statements are identified, they are put to use immediately in two places. (1) positive tests unrelated to these statements are filtered out from the original JUnit test suite, so that a reduced set of tests can be obtained for further use. (2) the scope of variables and methods is determined for the location of each of these statements.

Then the ingredient statements for each likely-buggy statement considered are selected from the seed statements in view of the current variable and method scope. For convenience, a likely-buggy statement along with the scope at its location and its corresponding ingredient statements is called a *modification point* in short.

Before entering into the genetic search, the types of operations on potentially buggy statements should be defined in advance. Similar to GenProg [9], ARJA uses three kinds of operations: *delete*, *replace*, and *insert*. More specifically, for each likely-buggy statement, ARJA either deletes it, replaces it with one of its ingredient statements, or inserts one of its ingredient statements before it. Although only three operation types are currently used, users can add other possible types [38] into ARJA easily due to its flexible design.

With a number of modification points, a subset of original JUnit tests, and the available operation types in place, ARJA encodes a program patch with a novel GP representation. Based on this new representation, a MOEA is employed to evolve the patches by simultaneously minimizing the failure rate on tests and patch size. Finally, the non-dominated solutions obtained with a failure rate of 0 are output as test-suite adequate patches.

Notably, ARJA is also characterized by a module that reduces the search space based on some specific rules. These rules fall into three different types that are specially designed for operation initialization, ingredient screening and decoding in multi-objective GP, respectively. Applying such rules allows the modified program to be compiled successfully with a higher probability, while focusing the search on more promising regions. of the search space.

3.2 Fault Localization and Coverage Analysis

For fault localization, ARJA uses an existing spectrum-based technique called Ochiai [39]. It computes a suspiciousness measure of a line of code (lc) as follows:

$$susp(lc) = \frac{N_{CF}}{\sqrt{N_F \times (N_{CF} + N_{CS})}} \tag{2}$$

where N_{CF} and N_{CS} are the number of negative tests and positive tests that visit the code lc, respectively, and N_F are the total number of negative tests. Fault localization analysis returns a number of potentially faulty lines, each represented as a tuple $(cls, lid, susp)$. cls and lid are the name of the Java class and the line number in this class, respectively, which are used to identify a line uniquely, and $susp \in [0, 1]$ is the corresponding suspiciousness score.

To look for seed statements, ARJA implements a strategy presented in [9] to reduce the number of seed statements and to choose those more related to the given JUnit tests. That is, coverage analysis is conducted to find the lines of code that are visited by at least one test, each of which forms a tuple (cls, lid).

After the above phases, the Eclipse AST parser is used to parse the potentially faulty lines and seed lines into the likely-buggy statements and seed statements respectively. For duplicate seed statements, only one of them is recorded. To conduct type/scope analysis latter, we explicitly request the binding service of the AST parser at parse time.

Note that in ARJA, we do not consider all potentially faulty statements. Instead, only a part of them is selected according to their suspiciousness in order to reduce the search space. The number of statements can be controlled in ARJA by either of two parameters denoted $\gamma_{\min}$ and $n_{\max}$. $\gamma_{\min}$ quantifies the minimum suspiciousness score for statements to be considered, while $n_{\max}$ determines that at most $n_{\max}$ likely-buggy statements with highest suspiciousness are chosen. If both $\gamma_{\min}$ and $n_{\max}$ are set, ARJA uses the smaller number determined by either of them.

3.3 Test Filtering

For each positive test, we record all the lines of code covered during its execution, and if these lines do not include any of the lines associated with the likely-buggy statements selected, we can filter out this positive test. This strategy can significantly speed up the fitness evaluation in GP.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

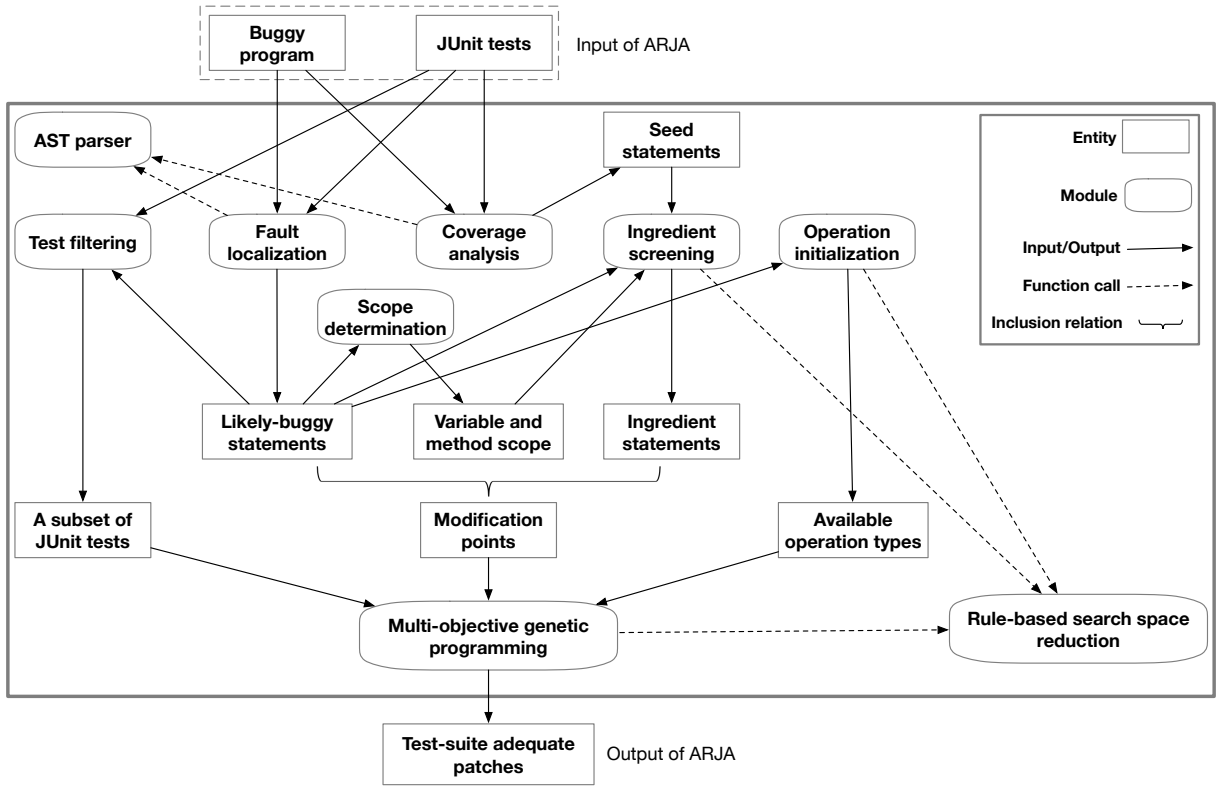

Fig. 5. Overview of the proposed automated program repair approach, i.e., ARJA.

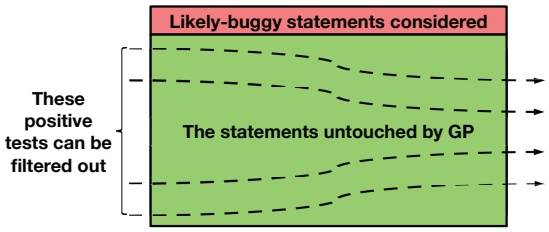

Fig. 6. Illustration of the execution path of the positive test that can be filtered out.

Note that test filtering may not guarantee correctness given that Java is a complex object-oriented language [40]. In this paper, we post-validate the final patches by ARJA on the original test suites to make this technique more reliable.

3.4 Scope Determination

For each likely-buggy statement considered, most seed statements cannot become an ingredient statement. This is mainly because these seed statements access variables or methods that are invisible at the location of the likely-buggy statement. To identify as many of them as possible, we have to determine the scope (i.e., all the visible variables and methods) at that location.

Note that unlike GenProg [9], ARJA considers not only the *variable* scope but also the *method* scope, which can improve the chance of the modified Java program to being compiled successfully. Suppose Cls and Med are the class and the method where a likely-buggy statement appears, respectively. According to the Java language specification, ARJA collects three kinds of variables to constitute the variable scope: the visible field variables in Med, the parameter variables of Med, and the local variables in Med defined before the location of the likely-buggy statement. Among them, the first kind of variables has three sources: the field variables declared in Cls, the field variables inherited from the parent classes of Cls, and the field variables declared in the outer classes (if they exist) of Cls. As for the method scope, ARJA collects the visible methods in Med, which have three sources similar to the visible field variables.

Note that besides the variable and method names, ARJA also records their type information and modifiers to make the scope more accurate. For a method, the type information includes both parameter types and the return type.

3.5 Ingredient Screening

This procedure aims to select the ingredient statements for each likely-buggy statement considered. In this phase, ARJA first adopts the *location awareness* strategy introduced in [41]. This strategy defines three alternative ingredient modes (i.e., *File*, *Package*, *Application*), which are used to specify the places where ingredients are taken from. Suppose a likely-buggy statement is located in the file Fl that belongs to the package Pk, then the "File" and "Package" modes mean that this likely-buggy statement can only take its ingredient statements from Fl and Pk, respectively. The "Application" mode means that the ingredient statements can come from anywhere in the entire buggy program. Compared to the "Application" mode, the other two modes can significantly restrict the space of ingredients, which may help to find the repairs faster or find more of them.

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

With the location awareness strategy incorporated, ARJA provides the following two alternative approaches for ingredient screening, namely a direct approach and a type matching based approach.

3.5.1 Direct Approach

The direct approach works as follows. For each considered likely-buggy statement, all the seed statements are examined one by one. If a seed statement does not come from the place specified by the ingredient mode, it will just be ignored. Otherwise, we extract the variables and methods accessed by this seed statement. For example, for the following statement:

```
ret = 1.0 - getDistribution().beta +
    b.regularizedBeta(getProbability(),
    this.x + 1.0, getTrials() - this.x);
```

the extracted variables include `ret`, `b`, and `x`; and the extracted methods are `getDistribution`, `getProbability` and `getTrials`. Note that for the sake of simplicity, we do not consider the variable beta and the method regularizedBeta, because their accessibility usually depends on the visibility of getDistribution and b, respectively.

For each extracted variable/method, we check whether the one with the same name and the compatible type exists in the variable/method scope (determined in Section 3.4). Only when all of them have the corresponding ones in the variable/method scope, this seed statement can become an ingredient statement of the likely-buggy statement.

3.5.2 Type Matching Based Approach

As mentioned in Section 2.4.4, it could be demanding for a seed statement to only access the variables/methods visible at the location of the likely-buggy statement. Indeed, the pattern of a seed statement can sometimes also be useful.

To exploit such patterns, the type matching based approach goes a step further compared to the direct approach. When certain variables or methods extracted from a seed statement cannot be found in the variable or method scope, the type matching based approach does not discard this seed statement immediately. Instead, it tries to map each variable or method out of scope to one with the compatible type in scope. To restrict the complexity, we follow three guidelines in type matching: 1) Different variables/methods in a seed statement must correspond to different ones in the scope; 2) If there is more than one variable/method with a compatible type, the one with the same type is preferred; 3) If there are multiple variables with the same priority, we just randomly choose one.

If the type matching is successful, the modified seed statement will become an ingredient statement. Fig. 7 and Fig. 8 illustrate how type matching works for variables and methods respectively, using toy programs.

In Fig. 7, the statement at line 3 is faulty, and the bug can be fixed by inserting `y=-y` before this statement. ARJA cannot repair this fault without type matching since no such fix ingredient exists in the current program. However, if type matching is enabled, `y=-y` can be generated via a seed statement `p=-p`, by mapping the variable `p` to `y`. Similarly, in Fig. 8, the method `fun` is mapped to `sub`, and an ingredient

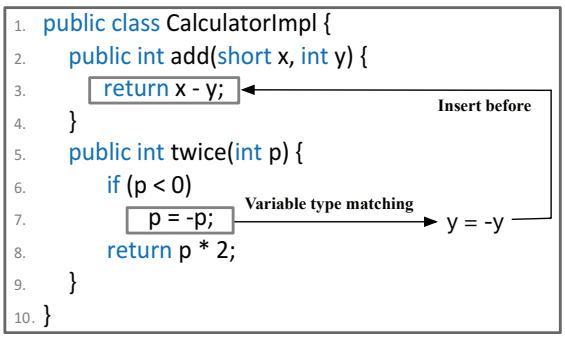

Fig. 7. Illustration of the type matching for variables.

statement `sub(x,-y)` is generated via `fun(x,-y)`, which can be used to fix the bug at line 3.

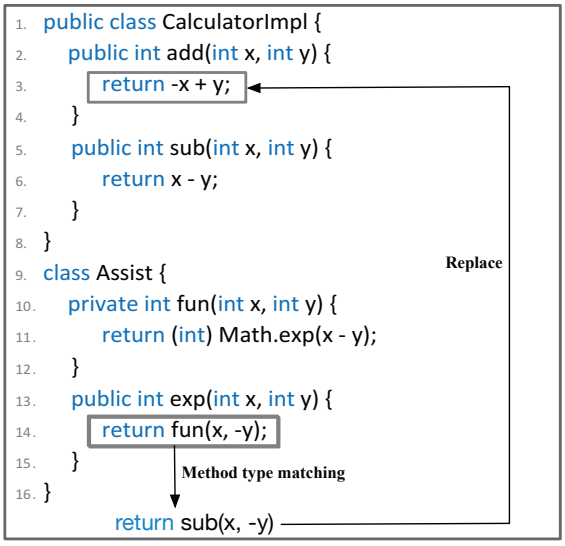

Fig. 8. Illustration of the type matching for methods.

3.6 Evolving Program Patches

Suppose that we have selected n likely-buggy statements using the procedure in Section 3.2, and each of them has a set of ingredient statements found by the method in Section 3.5. Thus, we have n modification points, each of which has a likely-buggy statement and its corresponding ingredient statements.

With the n modification points along with the available operation types and a reduced set of JUnit tests (obtained in Section 3.3), we can now encode a program patch as a genome and evolve a population of such tentative patches via multi-objective GP. The details are given as follows.

3.6.1 Solution Representation

To encode a patch, we first arrange the n modification points of a list in random order. For the j-th modification point, where $j = 1, 2, \ldots, n$, the corresponding set of ingredient statements is denoted by I_j and the statements in I_j are also ordered arbitrarily. Moreover, the set of operation types is denoted by O and the elements in O are numbered starting from 1. Note that the ID number for each modification point,

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

each statement in I_j, or each operation type in O is fixed throughout the evolutionary process.

In ARJA, we propose a new patch representation that can decouple the search subspaces of likely-buggy locations, operation types and ingredients perfectly. Specifically, each solution can be represented as $\mathbf{x} = (\mathbf{b}, \mathbf{u}, \mathbf{v})$, which contains three different parts and each part is a vector with size n.

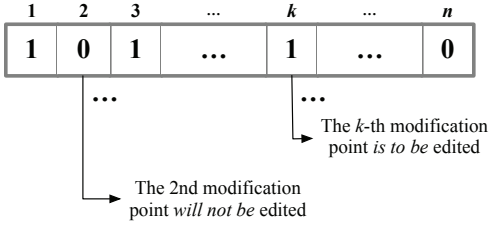

Fig. 9. Illustration of the first part (i.e., $\mathbf{b}$) of the representation.

The first part, denoted by $\mathbf{b} = (b_1, b_2, \ldots, b_n)$, is a binary vector with n bits b_j ($b_j \in \{0, 1\}, j = 1, 2, \ldots, n$). b_j indicates whether or not the patch $\mathbf{x}$ chooses to edit the likely-buggy statement in the j-th modification point. Fig. 9 illustrates the representation of $\mathbf{b}$.

The second part, denoted by $\mathbf{u} = (u_1, u_2, \ldots, u_n)$, is a vector with n integers, where $u_j \in [1, |O|], j = 1, 2, , \ldots, n$. u_j means that the patch $\mathbf{x}$ chooses the u_j-th operation type in the set O for the j-th modification point. In Fig. 10, we illustrate the representation of $\mathbf{u}$.

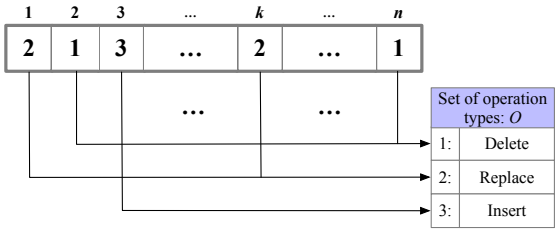

Fig. 10. Illustration of the second part (i.e., $\mathbf{u}$) of the representation.

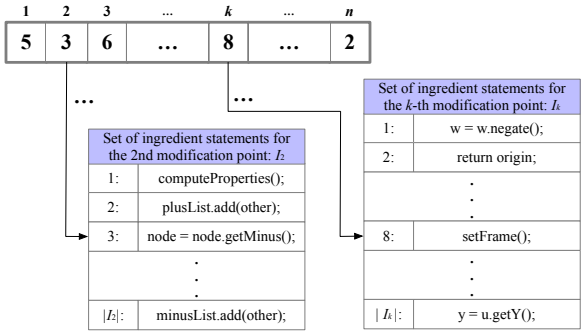

Fig. 11. Illustration of the third part (i.e., $\mathbf{v}$) of the representation.

Similar to $\mathbf{u}$, the third part (i.e., $\mathbf{v} = (v_1, v_2, \ldots, v_n)$) is also a vector with n integers, where $v_j \in [1, |I_j|], j = 1, 2, \ldots, n$. v_j indicates that the patch $\mathbf{x}$ chooses the v_j-th ingredient statement in the set I_j for the j-th modification point. Fig. 11 illustrates the representation of $\mathbf{v}$.

As can be seen, b_j, u_j and v_j together determine what the patch $\mathbf{x}$ does to the j-th modification point. For example, for the patch represented in Figs. 9, 10 and 11, it replaces the likely-buggy statement in the k-th modification point with `setFrame()`. Suppose the operation types in O are numbered as in Fig. 10, the whole procedure to apply a patch $\mathbf{x}$ (i.e., the decoding procedure) is described in Algorithm 1.

Algorithm 1: The procedure to apply a patch $\mathbf{x}$

Input: n modification points; the set of operation types O; a patch $\mathbf{x} = (\mathbf{b}, \mathbf{u}, \mathbf{v})$.
Output: A modified program.

```
for j = 1 to n do
    if b_j = 1 then
        st ← the likely-buggy statement in the j-th modification point;
        if u_j = 1 then
            Delete st;
        else
            st* ← the v_j-th ingredient statement in I_j;
            if u_j = 2 then
                Replace st with st*;
            else if u_j = 3 then
                Insert st* before st;
```

3.6.2 Population Initialization

For a specific problem, it is usually better to use the initialization strategy based on prior knowledge instead of random initialization, which could help genetic search find desirable solutions more quickly and easily.

In ARJA, we initialize the first part (i.e., $\mathbf{b}$) of each solution by exploiting the output of fault localization. Suppose $susp_j$ is the suspiciousness of the likely buggy statement in the j-th modification point, then b_j is initialized to 1 with the probability $susp_j \times \mu$ and 0 with $1 - susp_j \times \mu$, where $\mu \in (0, 1)$ is a predefined parameter. The remaining two parts (i.e., $\mathbf{u}$ and $\mathbf{v}$) of each solution are just initialized randomly (i.e., u_j and v_j are initialized to an integer randomly chosen from $[1, |O|]$ and $[1, |I_j|]$ respectively).

3.6.3 Fitness Evaluation

In ARJA, we formulate automated program repair as a multi-objective search problem. To evaluate the fitness of a solution $\mathbf{x}$, we propose a multi-objective function to simultaneously minimize two objectives, namely *patch size* (denoted by $f_1(\mathbf{x})$) and *weighted failure rate* (denoted by $f_2(\mathbf{x})$).

The patch size is given by Eq. (3), which indeed refers to the number of edit operations contained in the patch.

$$f_1(\mathbf{x}) = \sum_{i=1}^{n} b_i \tag{3}$$

The weighted failure rate measures how well the modified program (obtained by applying the patch $\mathbf{x}$) passes the given tests. We can formulate it as follows:

$$f_2(\mathbf{x}) = \frac{|\{t \in T_f \mid \mathbf{x} \text{ fails } t\}|}{|T_f|} + w \times \frac{|\{t \in T_c \mid \mathbf{x} \text{ fails } t\}|}{|T_c|} \tag{4}$$

where T_f is the set of negative tests, T_c is the reduced set of positive tests obtained through test filtering, and $w \in (0, 1]$ is a global parameter which can introduce a bias toward

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

negative tests. If $f_2(\mathbf{x}) = 0$, $\mathbf{x}$ does not fail any test and represents a test-adequate patch.

By simultaneously minimizing f_1 and f_2, we prefer test-adequate patches of smaller size. Note that if the modified program fails to compile or runs out of time when executing the tests, we set both of the objectives to $+\infty$. Moreover, $f_1 = 0$ is meaningless for program repair since no modifications are made to the orginal program. So, once f_1 is equal to 0 for a solution $\mathbf{x}$, f_1 and f_2 are immediately reset to $+\infty$, forcing such solutions to disappear with elite selection.

3.6.4 Genetic Operators

The genetic operators (i.e., crossover and mutation) are executed to produce offspring solutions in GP. To inherit good traits from parents, crossover and mutation are applied to each part of the solution representation separately.

For the first part (i.e., $\mathbf{b}$), we use half uniform crossover (HUX) and bit-flip mutation. As for both of the remaining parts (i.e., $\mathbf{u}$ and $\mathbf{v}$), we adopt single-point crossover and uniform mutation, because of their integer encoding. Fig. 12 illustrates how crossover and mutation are executed on two parent solutions. For brevity, only one offspring is shown in this figure.

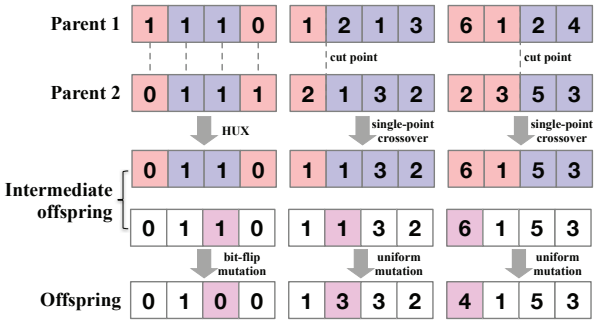

Fig. 12. Illustration of crossover and mutation in ARJA.

3.6.5 Using NSGA-II

Generally, based on the proposed solution representation, any MOEA can serve the purpose of evolving the patches for a buggy program. In ARJA, we employ NSGA-II [21] as the search algorithm, which is one of the most popular MOEA.

The NSGA-II based search procedure for finding test-adequate patches can be summarized as follows. First, an initial population with N (the population size) solutions is produced by using the initialization strategy presented in Section 3.6.2. Then the algorithm goes into a loop until the maximum number of generations is reached. In each generation g, binary tournament selection [21] and the genetic operators described in Section 3.6.4 are applied to the current population P_g to generate an offspring population Q_g. Then the N best solutions are selected from the union population $U_g = P_g \cup Q_g$ by using fast non-dominated sorting and crowding distance comparison (based on the two objectives formulated in Section 3.6.3). The resulting N best solutions constitute the next population P_{g+1}.

Finally, the obtained non-dominated solutions with $f_2 = 0$ are output as test-adequate patches found by ARJA. If no such solutions exist, ARJA fails to fix the bug.

3.7 Rule-Based Search Space Reduction

ARJA provides three types of rules that can be integrated into its three different procedures (i.e., operation initialization, ingredient screening and solution decoding) respectively. By taking advantage of these rules, we can not only increase the chance of the modified program to compile successfully, but also avoid some meaningless edit operations, thereby reducing the search space.

Note that when the rules are integrated into ARJA, the related procedures described in the previous subsections will be modified as discussed next.

3.7.1 Customizing the Operation Types

The first type of rules are used to customize the operation types for each modification point. Such rules are invoked in the operation initialization procedure since they only involve likely-buggy statements and the operation types.

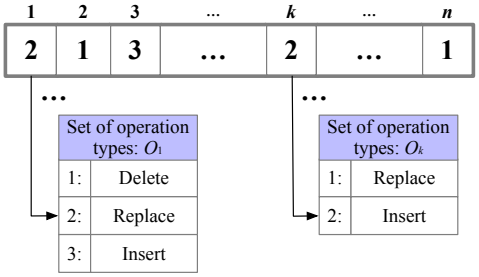

Fig. 13. Illustration of $\mathbf{u}$ for the purpose of customizing the operation types.

For a modification point, certain operation types in O may not be available according to the predefined rules. Currently in ARJA, we provide two rules of this type that are shown in Table 1. Suppose O_j is the set of available operation types for the j-th modification point, where $O_j \subseteq O, j = 1, 2, \ldots, n$. Fig. 13 illustrates the $\mathbf{u}$ vector for the purpose of customizing the operation types. Unlike in Fig 10, each modification point is associated with its own set of operation types (i.e., O_j), and u_j means that the patch chooses the u_j-th operation type in O_j (instead of O).

3.7.2 Further Filtering the Ingredients

The second type of rules concerns likely-buggy statements and the ingredient statements, which are employed to further filter the ingredient statements in an ingredient screening procedure. Such rules can help to remove undesirable ingredients which pass the scope check of variables and methods. For example, a `continue` statement does not contain any variable or method invocation, but it can only be used in a loop. Table 2 lists the rules of this type integrated into ARJA, and also explains their rationale.

By applying these rules to I_j (obtained by the procedure in Section 3.5), we can generate a reduced set I'_j where $I'_j \subseteq I_j$. I'_j will become the set of ingredients for the j-th modification point instead of I_j. To illustrate $\mathbf{v}$ in this scenario, we can just replace I_j with I'_j in Fig. 11, with v_j then indicating that the patch chooses the v_j-th ingredient statement in I'_j.

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

TABLE 1
The rules integrated in ARJA for customizing the operation types for each modification point

No.	Rule	rationale
1	Do not delete a variable declaration statement (VDS).	Deleting a VDS is usually very disruptive to a program, and keeping a redundant VDS usually does not influence the correctness of a program.
2	Do not delete a `return`/`throw` statement which is the last statement of a method not declared `void`.	Avoid returning no value from a method that is not declared `void`.

TABLE 2
The rules integrated in ARJA for further filtering the ingredients for each modification point

No.	Rule	rationale
1	The `continue` statement can be used as the ingredient only for a likely-buggy statement in the loop.	The keyword `continue` cannot be used out of a loop (i.e., `for`, `while` or `do-while` loop).
2	The `break` statement can be used as the ingredient only for a likely-buggy statement in the loop or in the `switch` block.	The keyword `break` cannot be used out of a loop (i.e., `for`, `while` or `do-while` loop) or a `switch` block.
3	A `case` statement can be used as the ingredient only for a likely-buggy statement in a `switch` block having the same enumerated type.	The keyworkd `case` cannot be used out of a `switch` block, and the value for a `case` must be the same enumerated type as the variable in the `switch`.
4	A `return`/ `throw` statement can be used as the ingredient only for a likely-buggy statement in a method declaring the compatible return/throw type.	Avoid returning/throwing a value with non-compatible type from a method.
5	A `return`/ `throw` statement can be used as the ingredient only for a likely-buggy statement that is the last statement of a block.	Avoid the unreachable statements.
6	A VDS can be used as the ingredient only for another VDS having the compatible declared type and the same variable names.	Avoid using an edit operation with no effect on the program or disrupting the program too much.

TABLE 3
The rules integrated in ARJA for disabling certain specific operations

No.	Rule	rationale
1	Do not replace a statement with the one having the same AST.	Avoid using an edit operation with no effect on the program.
2	Do not replace a VDS with the other kinds of statements.	Avoid disrupting the program too much.
3	Do not insert a VDS before a VDS.	The same with No. 1.
4	Do not insert a `return`/`throw` statement before any statement.	Avoid the unreachable statements.
5	Do not replace a `return` statement (with return value) that is the last statement of a method with the other kinds of statements.	Avoid returning no value from a method that is not declared void.
6	Do not insert an assignment statement before an assignment statement with the same left-hand side.	The same with No. 1.

3.7.3 *Disabling Certain Specific Operations*

The third type of rules involve at least the operation types and the ingredient statements. Such rules are used to ignore certain specific edit operations when decoding a solution $\mathbf{x}$ for fitness evaluation. Table 3 shows the rules of this type integrated in ARJA together with their rationale.

With these rules, if $b_j = 1$, the corresponding operation on the j-th modification point will not be conducted immediately as in Algorithm 1. Instead, we first check whether this operation conforms to one rule listed in Table 3. Once any of the rules is met, the operation will be disabled (equivalent to resetting b_j to 0).

4 Experimental Design

This section explains the design of our experimental study, including the research questions to be answered, the repair systems involved, the datasets of bugs used, and the evaluation protocol for comparing different repair approaches.

4.1 Research Questions

To conduct the general evaluation of ARJA, we seek to answer the following research questions in this study.

RQ1: Does random search really outperform genetic search in automated program repair?

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

Previous work by Qi et al. [12] claimed that random search outperforms GP in terms of both repair effectiveness and efficiency. Their work targeted C programs and was based on GenProg framework. We are interested in revisiting this claim based on ARJA that targets Java programs.

RQ2: What are the benefits of formulating program repair as a multi-objective search problem?

We would expect that the multi-objective formulation described in Section 3.6.3 can help ARJA generate simpler patches compared to a single-objective formulation. Besides this, we investigate whether the multi-objective formulation can provide other benefits.

RQ3: Is our proposed lower-granularity patch representation superior to that introduced by Oliveira et al. [20]?

In Section 2.4.1, we have analyzed the limitation of Oliveira et al.'s patch representation. Here we want to experimentally compare this representation with ours.

RQ4: Is ARJA better than state-of-the-art redundancy-based repair methods in terms of fixing multi-location bugs?

As stated in Section 1, one prominent feature of GP based repair approaches is that they have the potential to fix multi-location bugs. ARJA is a new GP based repair system, thus it is necessary to assess its superiority in this respect.

In RQs 1–4, our main concern is the *search ability* of ARJA (including its variants) and other related repair methods based on the redundancy assumption. So, here we only use ARJA *without* type matching for the simplicity and fair comparison. Moreover, all the involved approaches use the same fault localization module.

RQ5: How useful is the type matching strategy when the fix ingredients do not exist in the current buggy program?

Type matching can reasonably create ingredient statements that do not appear in the buggy program. We investigate whether these newly generated ingredients can be exploited effectively by ARJA to fix some bugs.

RQ6: How well does ARJA perform in fixing real-world bugs compared to several selected repair approaches?

It is of major interest to address real-world bugs in program repair. We need to know whether ARJA can work on real-world bugs in large-scale Java software systems, beyond fixing seeded bugs.

RQ7: To what extent can ARJA synthesize semantically correct patches for real bugs?

Since the empirical work by Qi et al. [13], it has been a hot question whether the patches generated by test-suite based repair approaches are correct beyond passing the test suite. We manually check the correctness of the patches synthesized by ARJA in our experiments.

RQ8: Why can't ARJA generate test-suite adequate patches for some real bugs?

Sometimes, ARJA fails to find any test-suite adequate patch. We examine several reasons for failure.

RQ9: How long is the execution time for ARJA on one bug?

The computational cost of one repair is also an important concern for users. We want to see whether the repair cost of ARJA is acceptable for practical use.

4.2 Repair Systems Under Investigation

There are mainly five repair systems involved in our experiments, which are ARJA, GenProg [9], RSRepair [12], Kali [13] and Nopol [35]. GenProg and RSRepair are selected since they are typical search-based repair approaches. The comparison of ARJA with them can demonstrate whether the proposed multi-objective GP enables stronger search ability, which is one of the major purposes of our study. Kali is used since it is a baseline system and can detect the weakness of test suites. Besides search-based repair approaches, we also want to include a semantic-based approach for comparison. Nopol is eventually selected since it is a representative approach of this kind and its source code is publicly available with active maintenance. Note that there are other well-known open-source repair tools, such as SemFix [15] and Prophet [42], but they are designed for C and cannot tackle Java bugs.

Our repair system, ARJA, is implemented with Java 1.7 on top of jMetal 4.5.[3] jMetal [43] is a Java based framework that includes a number of state-of-the-art EAs, particularly MOEAs. It is used to provide computational search algorithms (e.g., NSGA-II) in our work. ARJA parses and manipulates Java source code using the Eclipse JDT Core[4] package. The fault localization in ARJA is implemented with Gzoltar 0.1.1.[5] Gzoltar [44] is a toolset which determines suspiciousness of faulty statements using spectrum-based fault localization algorithms. Both coverage analysis and test filtering in ARJA are implemented with JaCoCo 0.7.9,[6] which is a Java code coverage library. For the sake of reproducible research, the source code of ARJA is available at GitHub.[7] In addition, several ARJA variants have also been implemented to answer different research questions.

RSRepair is a repair method that always uses the population initialization procedure of GenProg to produce candidate patches. Kali generates a patch by just removing or skipping statements. Strictly speaking, Kali cannot be regarded as a "program repair" technique, but it is a very suitable technique for identifying weak test suites or underspecified bugs [7]. GenProg, RSRepair, and Kali were originally developed for C programs. According to the details given in the corresponding papers [9], [12], [35], we carefully reimplement the three systems for Java under the same infrastructure of ARJA. Our source code for the three systems is publicly released along with ARJA.[7] Note that a program repair library named Astor [41] also provides the implementation of GenProg and Kali for Java, which are called jGenProg and jKali respectively in the literature [7], [41]. In addition, GenProg4J[8] is a Java based version of GenProg which is in active development. But to conduct controlled experiments, we only use our own implementation, unless otherwise specified.

Nopol is a state-of-the-art semantic-based repair method for fixing conditional statement bugs in Java programs. The code of Nopol[9] has been released by the original authors.

4.3 Datasets of Bugs

In our experiments, we use both seeded bugs and real-world bugs to evaluate the performance of repair systems.

To answer RQs 6–9, we adopt a dataset consisting of four open-source Java projects (i.e., JFreeChart,[10] Joda-Time,[11] Commons Lang, and Commons Math) from Defects4J [19]. Defects4J[12] has been a popular database for evaluating Java program repair systems [7], [45]–[48], because it contains well-organized real-world Java bugs. Table 4 shows the basic information of the 224 real-world bugs considered in Defects4J, where the number of lines of code and the number of JUnit tests are extracted from the latest buggy version of each project. Note that Defects4J indeed contains another two projects, namely Closure Compiler[13] and Mockito[14]. Following the practice in [7], [46], [47], we do not consider the two projects in the experiments. Closure Compiler is dropped since it uses the customized testing format rather than the standard JUnit tests; Mockito is ignored because it is a very recent project added into the Defects4J framework and its related artifacts are still in an unstable phase.

TABLE 4
The descriptive statistics of 224 bugs considered in Defects4J

Project	ID	#Bugs	#JUnit Tests	Source KLoC	Test KLoC
JFreeChart	C	26	2,205	96	50
Joda-Time	T	27	4,043	28	53
Commons Lang	L	65	2,295	22	6
Commons Math	M	106	5,246	85	19
Total		224	13,789	231	128

To address RQs 1–4, we use a dataset of seeded bugs rather than Defects4J. We think that Defects4J is not well suited to the purpose of distinguishing clearly the search ability of the repair systems considered. The reasons are listed as follows:

1) Many bugs (e.g., C2, L4 and M12) in Defects4J cannot be localized by state-of-the-art fault localization tools (e.g., Gzoltar). In such a case, fault localization rather than the search is responsible for the failure.
2) Although existing empirical studies [17], [18] validated the redundancy assumption by examining a large number of commits (16,071 in [17] and 15,723 in [18]), Defects4J contains a relatively small number of bugs and it may not conform well to this general assumption. Indirect evidence is that jGenProg can find patches for only 27 out of 224 bugs in Defects4J, as reported by Martinez et al. [7]. In such a case, it is the inadequate search space that matters, rather than the search ability.
3) As indicated in [7], among 27 bugs fixed by GenProg, 20 bugs can also be fixed by jKali. This means that for the overwhelming majority of these bugs, the search method can find a trivial patch (e.g., deleting a statement) that fulfills the test-suite by just focusing on a very limited search space. So, evaluation on such bugs cannot truly reflect the difference between redundancy-based repair methods in exploring a huge search space of potential fix ingredients.

The dataset of seeded bugs for RQs 1–4 are generated by the following procedures. First, we select the correct version of M85 as a target program, since it has a moderate number (i.e., 1983) of JUnit tests. Then, we randomly select k redundant[15] statements from two Java files (i.e., NormalDistributionImpl.java and PascalDistributionImpl.java). Last, we produce a buggy program by performing statement-level mutation (i.e., deletion, replacement or insertion) to each of the k statements. Note that not every buggy program obtained in this way is a suitable test bed, we choose some of them according to the following principles:

1) The fault localization technique can identify all the faulty locations of the seeded bug. This rules out the influence of fault localization.
2) Any nonempty subset of the k mutations should make at least one test fail. Generally, this ensures that the seeded bug is a multi-location bug when $k > 1$.
3) Kali cannot generate any test-suite adequate patch for the seeded bug. This challenges the search ability in finding nontrivial or complex repairs.

We vary k from 1 to 3 and finally collect a dataset containing 13 bugs of this kind, denoted by F1–F13. Among the 13 bugs, k is set to 1 for F1 and F2, 2 for F3–F9, and 3 for F10–F13. So all bugs except F1 and F2 are multi-location bugs. Because the mutated statements are redundant, the redundancy-based repair systems (e.g., GenProg and RSRepair) can fix any bug in this dataset, assuming that their search ability is strong enough. Note that the bugs with larger k values usually pose greater challenges since fix ingredients for more buggy locations need to be searched. Here we only consider $k \leq 3$ to restrict the complexity.

For RQ5, we use a similar method to generate a dataset of seeded bugs. The difference is that among the k statements to be mutated, at least one is non-redundant. So, it is expected that the redundancy assumption does not completely hold for such bugs, which can be used to verify the effectiveness of the type matching strategy. We set k to 2 and collect 5 bugs in this category, denoted by H1–H5.

To facilitate experimental reproducibility, we make the two datasets of seeded bugs available on GitHub as well.[16]

4.4 Evaluation Protocol

In our experiments, we always use "Package" as the ingredient mode in ARJA, GenProg, and RSRepair, although there exist two other alternatives as introduced in Section 3.5. To reduce the search space, we integrate all three types of rules (see Section 3.7) into ARJA. When investigating RQs

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

1–4, the direct approach (see Section 3.5.1) is used in ARJA for ingredient screening.[17] To save computational time, we employ the test filtering procedure (see Section 3.3) in all repair approaches implemented by ourselves (i.e., ARJA, GenProg, RSRepair, and Kali).

TABLE 5
The parameter setting for ARJA in the experiments

Parameter	Description	Value
N	Population size	40
G	Maximum number of generations	50
$\gamma_{\min}$	Threshold for the suspiciousness	0.1
$n_{\max}$	Maximum number of modification points	40
μ	Refer to Section 3.6.2	0.06
w	Refer to Section 3.6.3	0.5
p_c	Crossover probability	1.0
p_m	Mutation probability	$1/n$

Table 5 presents the basic parameter setting for ARJA in the experimental study, where n is the number of modification points determined by $\gamma_{\min}$ and $n_{\max}$ together (see Section 3.2). To ensure a fair comparison, parameters N, G, $\gamma_{\min}$ and $n_{\max}$ in GenProg and RSRepair are set to the same values as shown in Table 5. The global mutation rate in GenProg and RSRepair is set to 0.06 since it is similar to parameter μ in ARJA. Corresponding to $w = 0.5$, negative tests are weighted twice as heavily as positive tests in fitness evaluation of GenProg and RSRepair. Each trial of ARJA, GenProg and RSRepair is terminated after the maximum number of generations is reached. Moreover, in Kali, we also use $\gamma_{\min}$ and $n_{\max}$ to restrict the number of modification points considered. Their values are set to 0.1 and 40 respectively. Note that different parameter settings (e.g., population size) may influence the performance of ARJA, but parameter tuning would be very computationally expensive. In our experiments, we use the common settings based on GenProg and NSGA-II. Even with this basic setting we have already achieved promising results. Parameter tuning will be investigated in the future work.

ARJA, GenProg, and RSRepair are all stochastic search methods. To compare their search ability properly, each of these algorithms performs 30 independent trials for each seeded bug considered in RQs 1–5. There are several metrics involved for evaluating the search performance, which are explained as follows:

1) "Success": the number of trials that produce at least one test-suite adequate patch among 30 independent trials. This is regarded as the primary metric.
2) "#Evaluations" and "CPU (s)": the average number of evaluations and the average CPU time needed to find the first test-suite adequate patch in a successful trial.
3) "Patch Size": the average size of the smallest test-suite adequate patch obtained in a successful trial. Here "size" means the number of edits contained in a patch.
4) "#Patches": the average number of different test-suite adequate patches found in a successful trial. Note that we may obtain test-suite adequate patches with various sizes in a trial, this metric only counts the number of those with the smallest size. Moreover, the difference between patches here is judged in terms of syntactics rather than semantics.

To test the difference for statistical significance, we conduct the 1-sided t-tests at a 5% significance level on the assessment results obtained by two competing algorithms. *Significantly* better results are marked with "†".

Following the practice in [7], we perform only one trial of ARJA, GenProg, and RSRepair for most of real-world bug considered in RQ6, in order to keep experimental time acceptable. However, we note that multiple trials are needed to rigorously assess the performance of ARJA, GenProg, and RSRepair due to their stochastic nature. We discuss this important threat to validity in Section 7.

Our experiments were all performed in the MSU High Performance Computing Center.[18] We use 2.4 GHz Intel Xeon E5 processor machines with 20 GB memory.

5 Experimental Results on Seeded Bugs

This section presents our experimental results on seeded bugs in order to address RQs 1–5 set out in Section 4.1.

5.1 Genetic Search vs. Random Search (RQ1)

To compare the performance of genetic search with random search under the ARJA framework, we implemented an ARJA variant denoted as ARJA$_r$. The only difference between ARJA and ARJA$_r$ lies in that ARJA$_r$ always uses the initialization procedure of ARJA to generate candidate solutions and does not use the genetic operators described in Section 3.6.4. So, ARJA$_r$ purely depends on the random search and there is no cumulative selection. The relationship between ARJA and ARJA$_r$ is similar to that between GenProg and RSRepair. For a fair comparison, ARJA$_r$ also uses the parameters shown in Table 5 (excluding p_c and p_m).

Table 6 compares ARJA and ARJA$_r$ on F1–F13 in terms of the metrics "Success" and "#Evaluations". In this table, the meaning of k can be referred to in Section 4.3 and $|T_f|$ is the number of negative tests that trigger the bug. For brevity, the two columns will be omitted later in Tables 7 and 9.

As can be seen from Table 6, on all the bugs considered except F2 and F5, ARJA achieves a much higher success rate and also requires less number of evaluations to find a repair compared to ARJA$_r$. Moreover, ARJA is much more effective than ARJA$_r$ in synthesizing multi-line patches. For example, on each of F10–F13 which need at least three edit operations, ARJA$_r$ cannot find any test-suite adequate patch in any of the 30 trials, whereas ARJA still maintains good performance and succeeds in the majority of trials. For the bug F5, ARJA$_r$ appears more efficient since it can find a repair more quickly, but its repair success rate is very low (3 out of 30) and it is therefore not reliable. In contrast to ARJA$_r$, ARJA can always succeed in fixing the bug F5. As for F2, ARJA$_r$ performs slightly better than ARJA. The possible reason is that the fix of F2 only requires one insertion operation and ARJA$_r$ focuses more on a search space containing such simple repairs.

In summary, ARJA significantly outperforms ARJA$_r$ in terms of both repair effectiveness and efficiency, particularly

[17] Hereafter, if "ARJA" represents a specific algorithm, it refers to the version that uses the direct approach for ingredient screening. The ARJA variants using type matching will be differentiated by subscripts

F10	3	6	18†	0	936.11†	–
F11	3	6	20†	0	777.70†	–
F12	3	8	28†	0	742.04†	–
F13	3	4	20†	0	762.30†	–

[1] The metrics used in Tables 6–10, 12 are defined in Section 4.4
"–" means the data is not available.
"†" means the result is significantly better.

on multi-location bugs, which indicates that genetic search is indeed more powerful than random search in automated program repair.

Note that our conclusion here contradicts that drawn by Qi et al. [12]. This can be attributed to the fact that the two studies are based on different algorithmic frameworks and different subject programs. In [12], GenProg and RSRepair were compared on 24 C bugs from the GenProg benchmark. As pointed out in [13], almost all the patches reported by GenProg and RSRepair for these 24 bugs are equivalent to a single functionality deletion modification. When searching such trivial repairs, the crossover operator in GenProg will become ineffective. The main reason is that GenProg crossover works on the high-granularity edits (as mentioned in Section 2.4.1) and produces a new patch just by combining the edits from two parent solutions without creating any new material. But it is clear that the recombination of existing edits will not be helpful to find a patch that contains only a single edit. In addition, because RSRepair always uses the initialization procedure of GenProg, it has a very high chance to generate patches with only one edit when using a small global mutation rate (e.g., 0.06). Whereas in GenProg, the new edits will be appended to the existing patch, which means that GenProg intends to explore larger patches during the search. Nevertheless, this search characteristic of GenProg may make it less efficient than RSRepair in finding trivial patches that are test-suite adequate for the bugs considered in [12]. We speculate that GenProg will outperform RSRepair in terms of generating nontrivial or complex repairs.

5.2 Multi-Objective vs. Single-Objective (RQ2)

To show the benefits of the multi-objective formulation, we develop an ARJA variant denoted as ARJA$_s$, which only minimizes the weighted failure rate (see Eq. (4)). To serve the purpose of single-objective optimization, ARJA$_s$ uses a canonical single-objective GA instead of NSGA-II to evolve patches. To ensure a fair comparison, the single-objective GA also employs binary tournament selection and the genetic operators introduced in Section 3.6.4, and the parameter setting of ARJA$_s$ is the same with that of ARJA.

TABLE 7
Comparison between multi-objective and single-objective formulations within the ARJA framework. (Average of 30 runs)

Bug Index	Success		Patch Size		#Patches	
	ARJA	ARJA$_s$	ARJA	ARJA$_s$	ARJA	ARJA$_s$
F1	30†	26	2.00†	3.04	16.50†	1.73
F2	17	13	1.35†	2.85	10.94†	1.54
F3	26†	4	2.12†	3.25	4.00	1.00
F4	13	10	2.23†	4.50	5.92†	1.40
F5	30	30	2.67	2.50	7.23†	4.27
F6	30	28	2.80†	3.86	9.77†	1.61
F7	25†	11	2.24†	5.91	6.00	1.27
F8	29†	22	2.14†	4.23	7.76†	1.50
F9	6†	0	2.33†	–	2.50†	–
F10	18†	11	3.00†	4.45	3.22†	1.09
F11	20	18	3.00†	6.11	3.20†	1.17
F12	28†	15	3.07†	4.07	6.61†	1.80
F13	20	15	3.15†	5.47	4.60†	1.27

"–" means the data is not available.
"†" means the result is significantly better.

In Table 7, we present the comparative results between ARJA and ARJA$_s$ on bugs F1–F13, where the metrics "Success", "Patch Size" and "#Patches" are considered. As expected, ARJA can really generate test-suite adequate patches that contain smaller number of edits. The only exception is F5, where the patch sizes obtained by ARJA and ARJA$_s$ have no obvious difference. Moreover, it can be seen that the average patch size obtained by ARJA is usually very close to the corresponding k value (see Table 6) of the bug, demonstrating the effective minimization of f_1 (see Eq. (3)) by NSGA-II. According to "#Patches", for every bug, ARJA can find notably more different test-suite adequate patches than ARJA$_s$ in a successful trial, which is expected to provide more adequate choice for the programmer.

More interestingly, in terms of "Success" metric, we find that ARJA also clearly outperforms ARJA$_s$. Considering that this metric only concerns the weighted failure rate (f_2 formulated in Eq. (4)), our results suggest that the simultaneous minimization of f_1 and f_2 promotes the minimization of f_2 significantly. So, in the sense of search or optimization, f_1 can be seen as a helper objective in our multi-objective formulation of program repair. A similar phenomenon was also observed by some previous studies [49]–[51] on other applications, which is formally termed as *multi-objectivization* [49] in the literature. One possible reason for this improvement is that a helper objective can guide the search toward solutions containing better building blocks and helps the search to escape local minima [50].

To sum up, the multi-objective formulation helps to find simpler repairs (containing smaller number of edits) and also helps to find more of them. Furthermore, the multi-objective formulation can facilitate more effective search of test-suite adequate patches compared to the single-objective formulation. It is worth pointing out that GenProg [4] minimizes the patch size via a post-processing delta debugging. In the future work, it would be interesting to further examine how ARJA performs in terms of simple patches when compared to this post-processing procedure.

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

5.3 Comparison of Patch Representations (RQ3)

To compare between patch representations, we implement another ARJA variant denoted as ARJA$_o$, which differs from ARJA only in that it uses the patch representation and associated genetic operators introduced in [20] instead of those presented in Sections 3.6.1 and 3.6.4. In ARJA$_o$, we use a crossover operator called OP1SPACE since it shows the best overall performance among the three ones proposed by Oliveira et al. [20]. For a fair comparison, ARJA$_o$ also uses the basic parameter setting in Table 5.

TABLE 8
Comparison between patch representations within the ARJA framework. (Average over 30 runs)

Bug Index	k	$\|T_f\|$	Success		#Evaluations	
			ARJA	ARJA$_o$	ARJA	ARJA$_o$
F1	1	3	30	29	297.67†	842.07
F2	1	4	17	11	492.71†	1058.64
F3	2	4	26	30†	494.24†	745.70
F4	2	6	13†	6	746.54†	1480.83
F5	2	8	30	29	384.63†	628.93
F6	2	4	30†	23	624.80†	1180.00
F7	2	3	25†	18	698.52†	1259.50
F8	2	6	29	29	376.21†	683.76
F9	2	2	6	5	1028.00	1387.80
F10	3	6	18†	0	936.11†	–
F11	3	6	20†	2	777.70†	1613.50
F12	3	8	28†	5	742.04	1093.00
F13	3	4	20†	0	762.30†	–

"–" means the data is not available.
"†" means the result is significantly better.

Table 8 compares ARJA with ARJA$_o$ on bugs F1–F15, where the metrics "Success" and "#Evaluations" are considered. Compared to ARJA$_o$, ARJA achieves significantly lower success rate only on bug F3, and always finds the first repair with fewer evaluations. It is interesting to note that the performance gap between ARJA and ARJA$_o$ on bugs with $k = 3$ is much larger than that on others. This implies that the search ability of ARJA$_o$ becomes weaker if more complex repairs are required to be found. A possible reason is that the destructive edits resulting from the OP1SPACE crossover hinder ARJA$_o$ from maintaining a longer list of genes that is potentially useful.

5.4 Strength in Fixing Multi-Location Bugs (RQ4)

Most existing program repair systems (e.g., Nopol) in the literature can only generate single point repairs. GenProg and RSRepair are two state-of-the-art repair approaches that can target multi-location bugs. To assess the strength of ARJA in multi-location repair, we compare it with GenProg and RSRepair on the bugs F3–F13. F1 and F2 are not considered here since they belong to single-location bugs.

Note that ARJA does not take advantage of GenProg and RSRepair when comparing them on F3–F13, because all three approaches are based on the redundancy assumption and the fix ingredients of F3–F13 exist in their search space.

Table 9 shows the comparative results of ARJA, GenProg and RSRepair on F3–F13. As can be seen, ARJA outperforms both GenProg and RSRepair on all the considered bugs in terms of success rate. Indeed, on most of these bugs, ARJA achieves a much higher success rate than its counterparts. Compared to GenProg and RSRepair, ARJA also generally requires much smaller number of evaluations to find a repair. Although GenProg achieves better "#Evaluations" on F9, the metric is computed only based on a single successful trial. Given that ARJA does more than GenProg and RSRepair in one fitness evaluation, we also report the results of "CPU (s)" to provide another reference for comparing the efficiency of the approaches. It can be seen that the overall CPU time consumed by ARJA is comparable to that by GenProg. Since RSRepair only fixes two bugs here with very low success rate, we cannot rate its efficiency. In terms of "Patch Size", ARJA usually finds a much simpler repair than GenProg. This could be explained by different search mechanisms of GenProg and ARJA. GenProg considers larger patches in each generation by appending new edits to the existing patches. So once GenProg cannot find a repair in the first few generations, it will usually obtain patches that contain a relatively high number of edits. Different from GenProg, ARJA prefers smaller patches throughout the search process. In addition, we find that GenProg performs significantly better than RSRepair on the multi-location bugs considered, which corroborates our speculation from Section 5.1.

In summary, ARJA exhibits critical superiority over two prominent repair approaches (i.e., GenProg and RSRepair) in fixing multi-location bugs.

5.5 Effect of Type Matching (RQ5)

To show the effect of the type matching, we introduce three additional ARJA variants denoted as ARJA$_v$, ARJA$_m$ and ARJA$_b$. They do not use the direct approach for ingredient screening. Instead, ARJA$_v$ uses the type matching strategy just for variables (illustrated in Fig. 7), ARJA$_m$ uses this strategy for just methods (illustrated in Fig. 8), and ARJA$_b$ conducts type matching for both variables and methods.

Table 10 compares ARJA (without type matching), ARJA$_v$, ARJA$_m$ and ARJA$_b$ on bugs H1–H5, where "Success" is used as the comparison metric. From Table 10 we can see that, ARJA cannot find any test-suite adequate patch for all the bugs except H4, whereas ARJA$_v$ or ARJA$_b$ have a good chance to fix these bugs. This indicates type matching is a promising strategy that can help ARJA to fix some bugs whose fix ingredients do not exist in the buggy program considered. However, ARJA$_m$ does not perform very well here, which may imply that type matching for methods struggles to generate the fix ingredients for bugs H1–H3 and H5. Note that ARJA can fix bug H4, which means that, in terms of semantics, the repair mode of H4 still follows the redundancy assumption.

Although ARJA$_v$ and ARJA$_b$ perform much better overall than ARJA on these bugs, we note that they fail to achieve a very high success rate, particularly on H1 and H3. Considering that ARJA$_v$ and ARJA$_b$ indeed search over a much larger space of ingredient statements than ARJA, a possible reason is that the larger search space poses a serious difficulty for the underlying genetic search. More CPU time may help ARJA$_v$ and ARJA$_b$ to overcome this difficulty.

To sum up, the type matching strategy shows good potential to generate useful ingredient statements. These

H2	2	6	0	24	0	20
H3	2	5	0	4	0	3
H4	2	2	28	16	25	19
H5	2	7	0	17	0	13

new ingredients can be exploited by the genetic search to fix bugs for which the redundancy assumption does not hold. However, the much larger search space also challenges the search ability of GP in the ARJA framework.

6 Experimental Results on Real Bugs

This section presents our experimental results on real-world bugs in order to address RQs 6–9 set out in Section 4.1.

6.1 Evaluation on Real-World Bugs (RQ6)

In this subsection, we conduct a large-scale experiment on the Defects4J dataset, in order to show the superiority of the proposed repair approaches in fixing real-world bugs. Our experiment here is similar to that by Martinez et al. [7] but involves a larger number of repair approaches. Specifically, we consider ARJA along with its three variants (i.e., ARJA$_v$, ARJA$_m$ and ARJA$_b$), GenProg, RSRepair and Kali, which are all implemented by ourselves under the same infrastructure. Moreover, for our comparison purposes, we also include the results of jGenProg, jKali and Nopol reported in [7] on the same dataset. Note that the time-out for all three approaches was set to three hours per repair attempt. According to the experiments by Martinez et al. [7], a larger time-out would not improve their effectiveness. The implemented approaches generally need less than 1.5 hours to find the first test-suite adequate patch (with very few exceptions) and we use a CPU environment similar to the one used in [7], so the comparison here is unlikely to favor our implemented approaches.

Table 11 summarizes the results of the ten repair approaches on 224 bugs considered in Defects4J. For each approach, we list the number of bugs fixed for each project. The detailed bug indexes can be seen in the supplemental material.[19] From Table 11, ARJA is able to fix the highest number of bugs among all the ten approaches, with a total of 59, which accounts for 26.3% of all the bugs considered. To our knowledge, none of the existing repair approaches in the literature can synthesize test-suite adequate patches for so many bugs on the same dataset.

```
1  // DateTimeZone.java
2  public long adjustOffset(long instant, boolean earlierOrLater) {
3  ...
4      instantAfter = FieldUtils.safeAdd(instantAfter, ((long)
5              hashCode()) * ((long)
6                      DateTimeConstants.MINUTES_PER_DAY));
7      return convertLocalToUTC(local, false, earlierOrLater ?
8          instantAfter : instantBefore);
9  }
```

Fig. 14. Test-suite adequate patch generated by ARJA$_b$ for the bug T17.

Although each of the three ARJA variants (using type matching) searches over a superset of ARJA's ingredient space, they do not repair a higher number of bugs compared to ARJA. The possible reason is that the search ability of GP is still not strong enough to handle such a large search space determined by type matching, which has also been mentioned in Section 5.5. However, we note that the three ARJA variants can fix few bugs that cannot be patched by any redundancy-based repair approach (including ARJA) in comparison. These bugs are T1, L13, L14 and M79 by ARJA$_v$; L58, M44 and M79 by ARJA$_m$; and T1, T17, L13, L14, L21 and M7 by ARJA$_b$. This demonstrates the effectiveness of type matching on some real-world bugs. For instance, only ARJA$_b$ synthesizes a test-suite adequate patch for T17, which is shown in Fig. 14. The statement inserted (lines 4–6 in Fig. 14) indeed does not exist in the buggy program considered, whereas the following statement does

```
minutes = FieldUtils.safeAdd(minutes,
    ((long) getDays()) * ((long)
    DateTimeConstants.MINUTES_PER_DAY));
```

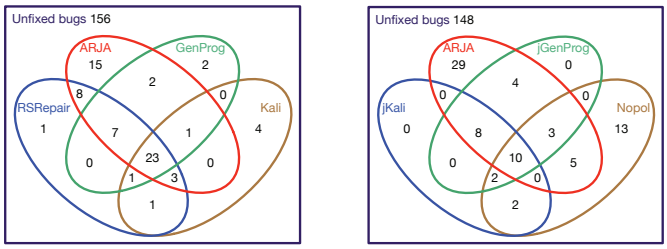
TABLE 11
Results for 224 bugs considered in Defects4J with ten repair approaches. For each approach on each project, we report the number of bugs where the test-suite adequate patches are found

Project	ARJA	$ARJA_v$	$ARJA_m$	$ARJA_b$	GenProg	RSRepair	Kali	jGenProg[1]	jKali[1]	Nopol[1]
JFreeChart	9	8	10	8	7	7	7	7	6	6
JodaTime	4	3	4	5	3	3	3	2	2	1
Commons Lang	17	13	15	15	9	9	9	0	0	7
Commons Math	29	20	29	21	17	25	14	18	14	21
Total	59 (26.3%)	44 (19.6%)	58 (25.9%)	49 (21.9%)	36 (16.1%)	44 (19.6%)	33 (14.7%)	27 (12.1%)	22 (9.8%)	35 (15.6%)

[1] The results are organized according to those reported in [7].

But the variable `minutes` and the method `getDays()` in this statement are both outside the scope of the faulty location. $ARJA_b$ maps the variable `minutes` to `instantAfter` and the method invocation `getDays()` to `hashCode()` through type matching, thereby inventing a new statement. $ARJA_b$ exploits GP to insert this new statement before line 7, which allows the patched program to fulfill the given test suite.



(a) ARJA, GenProg, RSRepair and Kali

(b) ARJA, jGenProg, jKali and Nopol

Fig. 15. Venn diagram of bugs for which test-suite adequate patches are found.

Another three repair approaches implemented by ourselves (i.e., GenProg, RSRepair and Kali) fix 36, 44 and 33 bugs respectively. To show their performance difference with ARJA more clearly, Fig. 15(a) presents a Venn diagram that shows the intersections of the fixed bugs among the four approaches. As seen from Fig. 15(a), the overwhelming majority of bugs handled by GenProg, RSRepair and Kali can also be handled by ARJA; ARJA is able to fix 15 bugs that neither GenProg, RSRepair nor Kali could fix; for 23 bugs, all the four repair approaches can generate a test-suite adequate patch. Note that on the Defects4J dataset considered, RSRepair can synthesize test-suite adequate patches for more bugs than GenProg. Further, we find that RSRepair generates a patch containing only a single edit for 41 out of 44 fixed bugs. Recall that the search mechanism of RSRepair is more suitable to find such very simple repairs than that of GenProg, as discussed in Section 5.1. So, it is not surprising that RSRepair shows a certain advantage over GenProg on the bugs considered here.

From Fig. 15(b), ARJA is clearly superior to jGenProg and jKali. Almost all the bugs repaired by jGenProg and jKali can also be repaired by ARJA. ARJA also fixes a greater number of bugs than Nopol, but their performance shows good complementarity: ARJA and Nopol can handle 41 and 17 bugs, respectively, that cannot be handled by the peer.

Considering the randomness of stochastic algorithms [52], we further statistically evaluate ARJA, GenProg and RSRepair on 12 real bugs in Defects4J. The 12 bugs are selected because they may require multiple edits according to a single run of the three approaches, and thus may pose a greater challenge to the search. Each repair approach performs 30 random trials on each bug. Table 12 shows the results, where $|T_f|$ is the number of negative tests that trigger the bug and the metric "Success" is reported for comparison. From Table 12, ARJA significantly outperforms both GenProg and RSRepair on all 12 bugs except L55 and M60, which again confirms the stronger search ability of ARJA compared to GenProg and RSRepair.

TABLE 12
Results for 12 real bugs with ARJA, GenProg and RSRepair (the metric "Success" is reported in this table)

Bug Index	$\|T_f\|$	ARJA	GenProg	RSRepair
T15	1	23†	1	0
L20	2	30†	0	0
L35	2	18†	1	0
L41	2	25†	0	0
L46	1	14†	3	4
L50	8	30†	12	2
L55	1	30	29	14
L61	2	13†	4	0
M22	3	30†	0	0
M56	1	20†	5	3
M60	1	3	3	3
M98	2	30†	0	0

"†" means the result is significantly better than the others.

To summarize, ARJA and its variants have an obvious advantage over the repair approaches evaluated in this experiment in handling real bugs. We find that the ten repair approaches considered in our experiment can synthesize a test-suite adequate patch for 88 out of total 224 bugs. To provide a reference for future research, the patches generated by our approaches are publicly available at GitHub.[20]

6.2 Patch Correctness (RQ7)

Because of a weak test suite used as oracle, a test-suite adequate patch for certain bugs may be incorrect though passing the given test suite, a condition called patch overfitting [13], [53]. In this subsection, we manually evaluate the correctness of the patches generated by ARJA.[21] We regard a test-suite adequate patch correct if it is exactly the same

[20] Defects4J patches, http://github.com/yyxhdy/defects4j-patches

[21] Due to limited manual effort, we currently do not consider the correctness of the patches found by the other approaches in comparison

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

as or semantically equivalent[22] to a human-written patch. Due to a lack of domain knowledge, we cannot confirm the correctness of the patches for some bugs, and do not include them in our manual assessment. To increase confidence, we avoid complex semantic analysis and identify a patch as correct only when we can provide detailed explanations that can be acknowledged by an external researcher.

TABLE 13
The bugs for which the correct patches are synthesized by ARJA

Project	Bug Index
JFreeChart	C3, C5, C12
Joda-Time	T15
Commons Lang	L20, L35, L43, L45
Commons Math	M5, M22, M39, M50, M53, M58, M70, M73, M86, M98
Total	18

After careful analysis, we find that ARJA can synthesize correct patches for at least 18 bugs in Defects4J, which are shown in Table 13. These results are very encouraging. This is because ARJA referred to here is also based on the redundancy assumption like jGenProg, but jGenProg can only correctly fix 5 bugs (as reported in [7]) which are also correctly repaired by ARJA. Among the remaining 13 bugs, jGenProg cannot even find a test-suite adequate patch for 11 of them. This again demonstrates the effectiveness of the improved GP search in ARJA. Nopol can only correctly fix 5 bugs (i.e., C5, L44, L55, L58 and M50), so ARJA also shows superiority over Nopol in finding correct patches. Furthermore, to our knowledge, only ARJA can generate a correct patch for bugs C12, L20, M22, M39, M58, M86 and M98, whereas the other repair systems ever tested on Defects4J cannot. Another highlight of ARJA is that it can correctly fix some multi-location bugs in Defects4J, which are hard to repair by the other repair methods.

To illustrate the expressive power, we conduct the case studies of the bugs that are correctly repaired by ARJA. We find that some of these repairs appear to be very interesting.

6.2.1 Case Study of Single-Location Bugs that are Correctly Repaired by ARJA

Among the bugs correctly fixed by ARJA, 13 can be categorized as single-location bugs since ARJA is able to repair them with only a single edit. Here we only take M58 and M86 as examples.

```
1  // GaussianFitter.java
2  public double[] fit () {
3        final double[] guess = (new
4           ParameterGuesser(getObservations())).guess();
5  -     return fit(new Gaussian.Parametric(), guess);
6  +     return fit((new ParameterGuesser(getObservations()))
7  +           .guess());
8  }
```

Fig. 16. Correct patch generated by ARJA for bug M58.

[22]Here it means two patched programs have the same functionality.

Fig. 16 shows the correct patch generated by ARJA for M58. It is syntactically different from the human-written patch that replaces the faulty statement (line 5) with `return fit(guess);`. Nevertheless, the method parameter in the statement inserted by ARJA (lines 6–7) is indeed equivalent to the variable `guess` according to the variable declaration statement (lines 3–4), and we have confirmed that the method invocations `ParameterGuesser`, `getObservations` and `guess` do not change anything outside the faulty method `fit()`. Thus the patch shown in Fig. 16 is semantically equivalent to the human-written patch.

```
1  // CholeskyDecompositionImpl.java
2  public CholeskyDecompositionImpl(...) {
3    for (int i = 0; i < order; ++i) {
4      final double[] lI = lTData[i];
5      if (lTData[i][i] < absolutePositivityThreshold) {
6        throw new NotPositiveDefiniteMatrixException();
7      } ...
8    }
9    for (int i = 0; i < order; ++i) {
10     final double[] ltI = lTData[i];
11 +   if (lTData[i][i] < absolutePositivityThreshold) {
12 +     throw new NotPositiveDefiniteMatrixException();
13 +   }
14       ...
15   } ...
16 }
```

Fig. 17. Correct patch generated by ARJA for the bug M86.

In Fig. 17, we show the correct patch found by ARJA for the bug M86. This bug occurs because the buggy program fails to correctly check whether a symmetric matrix is positive definite (the Cholesky decomposition only applies to the positive-definite matrix). The buggy program does such a check using the `if` statement at line 5 in Fig. 17, which examines whether all diagonal elements are positive. However this is only a necessary, though not sufficient, condition for the positive definite matrix. The human-written patch first deletes the `if` statement at line 5 and then inserts almost the same `if` statement (`lTData[i][i]` is equivalently changed to `ltI[i]`) before line 14, so that the validation of the positive definitiveness is conducted correctly during the decomposition process. Unlike the human-written patch, the correct patch by ARJA does not delete the `if` statement at line 5. Because this `if` statement states a necessary condition, just keeping it intact would not influence the correctness of the patched program.

6.2.2 Case Study of Multi-Location Bugs that are Correctly Repaired by ARJA

The bugs L20, L35, T15, M22 and M98 are classified as multi-location bugs, since ARJA fixes each of them correctly using more than one edit. For M22 and M98, ARJA can generate a correct patch that is exactly the same as the human-written patch. As for the remaining three, ARJA synthesizes semantically equivalent patches, which are analyzed as follows. In Fig. 18, we present a correct patch synthesized by ARJA for bug L20. The reason leading to this bug is that even if `array[startIndex]` is not equal to `null`, `array[startIndex].toString()` can still be `null`, and `array[startIndex].toString().length()` would

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

```
1  // StringUtils.java
2  public static String join(Object[] array, char separator, int
       startIndex, int endIndex) { ...
3  -   StringBuilder buf = new StringBuilder((array[startIndex] ==
4  -       null ? 16 : array[startIndex].toString().length()) + 1);
5  +   StringBuilder buf = new StringBuilder(256);
6     ...
7  }
8  public static String join(Object[] array, String separator, int
       startIndex, int endIndex) { ...
9  -   StringBuilder buf = new StringBuilder((array[startIndex] ==
10 -       null ? 16 : array[startIndex].toString().length()) +
11 -           separator.length());
12 +   StringBuilder buf = new StringBuilder(256);
13    ...
14 }
```

Fig. 18. Correct patch generated by ARJA for bug L20.

thereby cause the `NullPointerException`. A human developer fixes this bug by replacing two faulty statements (lines 3–4 and lines 9–11 in Fig. 18) with the same statement shown as follows:

```
StringBuilder buf = new
    StringBuilder(noOfItems * 16);
```

We find that the initial capacity (e.g., `noOfItems * 16` or 256) of `StringBuilder` has nothing to do with the correctness but with the performance. If the the initial capacity is too large, much unnecessary memory will be allocated; if it is too small, `StringBuilder` will frequently expand its capacity when accommodating additions, requiring more computational time. But in terms of making the buggy program functionally correct, the patch generated by ARJA has no difference with the human-written patch.

Fig. 19 shows the correct patch found by ARJA for bug L35. The buggy program fails to satisfy a desired behavior: the method `add(T[] array, T element)` should throw `IllegalArgumentException` when both parameters are `null`. The only difference between the patch by ARJA and the human-written patch lies in the detailed message of the exception. However, this difference will not affect the ability of the patched program by ARJA to meet the specified functionality successfully.

```
1  // ArrayUtils.java
2  public static <T> T[] add(T[] array, T element) {
3   ...
4  -   type = Object.class;
5  +   throw new IllegalArgumentException("The Integer did not
6  +     match any ...");
7   ...
8  }
9  public static <T> T[] add(T[] array, int index, T element) {
10  ...
11 -   return (T[]) new Object[] { null };
12 +   throw new IllegalArgumentException("The Integer did not
13 +     match any ...");
14  ...
15 }
```

Fig. 19. Correct patch generated by ARJA for bug L35.

ARJA fixes bug T15 correctly in an interesting way, as shown in Fig. 20. This bug occurs when `val1` and `val2` are equal to `Long.MIN_VALUE` and -1 respectively. In this scenario, the product should be `-Long.MIN_VALUE`. But `-Long.MIN_VALUE` exceeds the maximum allowed value (i.e., `Long.MAX_VALUE`) and the buggy program indeed returns an incorrect overflow. To fix this bug, a human developer just inserts the following `if` statement before line 5 in Fig. 20:

```
if (val1 == Long.MIN_VALUE) {
  throw new
      ArithmeticException("...overflows");
}
```

So in terms of the human-written patch, this bug can also be regarded as a single-location bug. However, ARJA cannot generate such a patch since the above `if` statement does not exist anywhere in the buggy program. As shown in Fig. 20, the patch by ARJA first replaces line 5 with a `break` statement to avoid returning an incorrect value there, then it detects the overflow that triggers the bug in the new `if` statement (lines 14–17) with the expression `val1 == Long.MIN_VALUE && val2 == -1`. Note that the boolean expression `val2 == Long.MIN_VALUE && val1 == -1` is always false since `val2` is an `int` value, so it has no effect and can be ignored. As can be seen, the patch by ARJA just does the same thing as the human-written patch in a different way, and thus it is correct.

```
1  // FieldUtils.java
2  public static long safeMultiply(long val1, int val2) {
3     switch (val2) {
4     case -1:
5  -  return -val1;
6  +  break;
7     case 0: return 0L;
8     case 1: return val1;
9     }
10    long total = val1 * val2;
11 -  if (total / val2 != val1) {
12 -     throw new ArithmeticException("...overflows");
13 -  }
14 +  if (total / val2 != val1 || val1 == Long.MIN_VALUE &&
15 +  val2 == -1 || val2 == Long.MIN_VALUE && val1 == -1) {
16 +     throw new ArithmeticException("...overflows");
17 +  }
18    return total;
19 }
```

Fig. 20. Correct patch generated by ARJA for bug T15.

6.2.3 *Other Findings*

Our manual study also provides other findings besides the correct patches for some bugs.

We find that although the test-suite adequate patches for a number of bugs (e.g., C1, C19, L7 and L16) may not be correct, they present some similarities with corresponding human-written patches. So these test-suite adequate patches would still be useful in assisting the human developer to create correct patches.

With stronger search ability, ARJA can identify more under-specified bugs than previous repair approaches (e.g., jGenProg and jKali). For example, Martinez et al. [7] claimed that the specification of the bug L55 by the test suite is

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

good enough to drive the generation of a correct patch, considering Nopol can repair this bug whereas jGenProg and jKali cannot. However we find that L55 is also an under-specified bug and an overfitting patch (shown in Fig. 21) that simply deletes two statements can fulfill its test suite.

```
1  // StopWatch.java
2  public void stop() {  ...
3  -   stopTime = System.currentTimeMillis();
4  -   this.runningState = STATE_STOPPED;
5  }
```

Fig. 21. Test-suite adequate but incorect patch for bug L55.

We have also checked the correctness of the patches by ARJA for seeded bugs and find that most of these test-suite adequate patches are correct. Recalling that Kali cannot uncover the weakness of the test suite for any seeded bug, this implies that a stronger test suite would render ARJA more able to generate correct patches. Several recent studies [47], [48], [54] have started to explore the potential of test case augmentation for program repair.

Moreover, we find that almost all the final multi-edit patches produced by ARJA cannot be reduced by delta-debugging to a single edit. The only exception is for bug L51. This phenomenon can be well understood, because ARJA explicitly minimizes the patch size during the search so that delta-debugging in a post-processing step is not needed.

6.2.4 Summary

In summary, through careful manual assessment, we find that ARJA can synthesize a correct patch for at least 18 bugs in Defects4J. To the best of our knowledge, some of the 18 bugs have never been fixed correctly by existing repair systems in the literature. Furthermore, ARJA is able to generate correct patches for several multi-location bugs, which is impossible for most of the other repair approaches.

Note that we do not focus on the number of correctly repaired bugs on the Defects4J dataset when comparing ARJA with other approaches that are *not* based on the redundancy assumption (e.g., Nopol). Nowadays, it is common knowledge that different kinds of repair techniques can be better at addressing different classes of bugs. For example, although Nopol that targets conditional statement bugs can only fix 5 bugs correctly on the same dataset [7], 3 of them cannot be repaired correctly by ARJA. So the number of correct fixes by different categories of repair techniques would strongly depend on how the dataset tested was built [14]. Also, we cannot expect that the 224 bugs in Defects4J can truly reflect the natural distribution of real-world bugs. For instance, Defects4J indeed contains a considerable number of null pointer bugs, so it may favor those approaches that can explicitly conduct null pointer detection with fix templates (e.g., PAR [55] and ACS [46]). Compared to such approaches, ARJA is a more generic repair approach.

In contrast, ARJA and jGenProg can be compared meaningfully on the Defects4J dataset in terms of the number of bugs fixed or correctly fixed, because both of them typically belong to redundancy-based repair techniques and use GP to explore the search space. ARJA performs much better than jGenProg, which clearly validates the improvement of GP search in ARJA.

To facilitate re-examination by the other researchers, we provide a detailed explanation of the correctness for each correct patch generated by ARJA, publicly available in the supplemental material.[19]

6.3 Reasons for Failure (RQ8)

As seen from the experimental results, ARJA and its variants sometimes fail to find a test-suite adequate patch for some bugs. We find that there are three possible reasons for failure, which are discussed in the following.

The first reason is that fix ingredients for the bug do not exist in the search space of the proposed repair approach. In this case, no matter how powerful the underlying genetic search is, ARJA (or its variants) will definitely fail to fix the bug. The failure of ARJA on many bugs such as T1 and M1 may be attributed to this reason.

The second reason is that although test-suite adequate (or even correct) patches exist in the search space, the search ability of GP is still not strong enough to find it within the required number of generations. An example is the failure of ARJA on the real bug L53. Fig. 22 shows a human-written patch for this bug. We find that ARJA takes into account lines 10 and 18 as potentially faulty lines by fault localization. So, a correct patch within the search space of ARJA consists of the following two edits: 1) insert the `if` statement located at line 6 before line 10; 2) insert the `if` statement located at line 14 before line 18. This patch is semantically equivalent to the human-written patch shown in Fig. 22. However, we note ARJA fails to find it under the parameter settings of our experiment. This may be because the genetic search is easily trapped in local optima when navigating the search space corresponding to L53.

```
1  // DateUtils.java
2  private static void modify(Calendar val, int field, boolean
       round) { ...
3    if (!round || millisecs < 500) {
4      time = time - millisecs;
5  + }
6      if (field == Calendar.SECOND) {
7        done = true;
8      }
9  - }
10   int seconds = val.get(Calendar.SECOND);
11   if (!done && (!round || seconds < 30)) {
12     time = time - (seconds * 1000L);
13 + }
14     if (field == Calendar.MINUTE) {
15       done = true;
16     }
17 - }
18   int minutes = val.get(Calendar.MINUTE);
19   ...
20 }
```

Fig. 22. Human-written patch for bug L53.

The last reason is that ARJA fails to consider the faulty lines that trigger the bug in the computational search, which can be further divided into the following three categories:

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

1) The fault localization technique adopted in ARJA fails to identify all faulty lines related to the bug of interest. This applies to bugs C2, T9, L4, M12, M104, and so on.
2) Due to the inadequate accuracy of fault localization, the faulty lines are given relatively low suspiciousness. For example, Fig. 23 shows the human-written patch for L10. We find that the suspiciousness for all these faulty lines is less than 0.2, but the number of lines with suspiciousness larger than 0.2 is more than 40 (i.e., $n_{\max}$ value in our experiments). Hence ARJA leaves out faulty lines and fails to fix this bug.

```
1  // FastDateParser.java
2  private static StringBuilder escapeRegex(StringBuilder
       regex,...) {
3  - boolean wasWhite = false;
4        ...
5  -   if (Character.isWhitespace(c)) {
6  -     if (!wasWhite) {
7  -       wasWhite = true;
8  -       regex.append("\\s*+");
9  -     }
10 -     continue;
11 -   }
12 -   wasWhite = false;
13       ...
14 }
```

Fig. 23. Human-written patch for bug L10.

3) The test suite is not adequate for the fault localization. Bug M46 provides an example of such a scenario, whose human written patch is shown in Fig. 24. We find that the whole method starting from line 8 is not covered by any negative test. So based on the current test suite of M46, the coverage-based fault localization technique, no matter how powerful, cannot identify line 10 as a potentially faulty line.

```
1  // Complex.java
2  public Complex divide(Complex divisor) throws
       NullArgumentException { ...
3    if (divisor.isZero) {
4  -   return isZero ? NaN : INF;
5  +   return NaN;
6    }   ...
7  }
8  public Complex divide(double divisor) { ...
9    if (divisor == 0d) {
10 -   return isZero ? NaN : INF;
11 +   return NaN;
12   } ...
13 }
```

Fig. 24. Human-written patch for bug M46.

Note that we can use simple strategies to alleviate the issues mentioned in the second and the third categories. For example, for bug L10, we just reset parameter $n_{\max}$ to 80 and then run ARJA again. As a result, ARJA can now find a test-suite adequate patch for L10 which simply deletes the `if` statement at line 5 in Fig. 23. This patch is semantically equivalent to the human written patch and is thus correct. As for M46, we modify the JUnit test named `testScalarDivideZero` as shown in Fig. 25. This JUnit test (before modification) is originally a positive test, because `x.divide(Complex.ZERO)` and `x.divide(0)` return the same incorrect value (i.e., `INF`) due to the faults in lines 4 and 10 in Fig. 24, and because this test only checks the equality rather than the individual values. We add a statement (line 4 in Fig. 25) that can expose the fault at line 10 in Fig. 24, and run ARJA again on M46 with the modified test suite. As a result, ARJA can now fix this multi-location bug and the patch obtained is exactly the same as the human-written patch.

```
1  // ComplexTest.java
2  public void testScalarDivideZero() {
3    Complex x = new Complex(1,1);
4  + TestUtils.assertEquals(x.divide(0), Complex.NaN, 0);
5    TestUtils.assertEquals(x.divide(Complex.ZERO),
6      x.divide(0), 0);
7  }
```

Fig. 25. The modification of an associated JUnit test of M46.

6.4 Repair Efficiency (RQ9)

For industrial applicability of automated program repair, an approach should fix a bug within a reasonable amount of time. Table 14 presents time (in minutes) for generating the first repair for the Defects4J bugs.

TABLE 14
Time cost of patch generation on Defects4J dataset

Repair Approach	CPU Time (in minutes)			
	Min	Median	Max	Average
Arja	0.73	4.70	63.73	10.02
Arja_v	0.86	4.63	80.63	10.32
Arja_m	0.86	4.67	37.85	10.49
Arja_b	0.89	5.27	95.12	11.48
GenProg	0.61	8.43	83.06	16.20
RSRepair	0.87	6.23	238.93	17.88
Kali	0.89	2.38	48.05	6.58

The CPU time is measured on an Intel Xeon E5-2680 V4 2.4 GHz processor with 20 GB memory.

According to Table 14, the median and average time for a successful repair by ARJA and its three variants is around 5 minutes and 10 minutes, respectively. However, maximal CPU time can reach more than one hour. GenProg and RSRepair are less efficient than ARJA and its variants, which further underlines the superiority of the ARJA framework. Kali is the most efficient on average, but it only considers trivial patches.

In summary, the repair efficiency of ARJA and its variants compares favorably with that of existing notable automatic repair approaches. Considering that ARJA consumes about 10 minutes on average and one hour at most for a repair in our experiments, we think that this efficiency is generally acceptable for industrial use in light of the bug-fixing time required by human programmers [56], [57].

7 Threats to Validity

In this section, we discuss three basic types of threats that can affect the validity of our empirical studies.

7.1 Internal Validity

To support a more reasonable comparison, we reimplemented GenProg, RSRepair and Kali for Java under the same infrastructure as ARJA. Although we faithfully and carefully followed the details described in the corresponding research papers during reimplementation, our implementation may still not perform as well as the original systems. There may even be bugs in the implemented systems that we have not found yet. To mitigate this threat, we make the code of the three systems available on GitHub for peer-review. Note that although jGenProg has been widely used as the the implementation of GenProg for Java [45]–[48], it was not implemented by the original authors of GenProg, thereby also potentially suffering from reimplementation issues. According to our results, our implemented GenProg indeed shows advantages over jGenProg.

In our experiments, we use the same parameter setting for all bugs considered. There is a risk that the parameter setting is poor for handling some bugs. Section 6.3 has shown an example where the resetting of $n_{\max}$ can allow ARJA to find a correct patch for bug L10. However it is not realistic to select an ideal parameter setting for every repair approach on every bug. We here use a uniform parameter setting among the implemented repair approaches to ensure a fair comparison.

Another internal threat to validity concerns the stochastic nature of ARJA (including its variants), GenProg and RSRepair. It is possible that different runs of these repair approaches would obtain somewhat different results. We run each of them only once on each of 224 bugs in Defects4J, which may lead to an overestimation or underestimation of their repair effectiveness on this dataset. However, our experiments on the Defects4J dataset have already been much larger in scale than those conducted by Martinez et al. [7], since it involved a larger number of repair methods (i.e., 7 methods) and repair trials (i.e., 1,568 trials).

7.2 External Validity

Our experimental results are based on both seeded bugs and real-world bugs.

Although the seeded bugs F1–F15 are randomly produced, there still exists the possibility that the fitness landscapes corresponding to these bugs favor a certain kind of search mechanism. So the evaluation on these bugs may not reflect the actual difference in search ability between different search strategies (i.e., multi-objective GP, single-objective GP and random search).

For real-world bugs, we used 224 bugs of four Java projects from Defects4J. However, it is not possible to expect that such a number of bugs can fully represent the actual distribution of defect classes and difficulties in the real world. So the evaluation may not be adequate enough to reflect the actual effectiveness of our repair techniques on real-world bugs, and our results may also not generalize to other datasets. However, Defects4J is known to be the most comprehensive dataset of real Java bugs currently available, and it has been extensively used as the benchmark for evaluating Java program repair systems [7], [45]–[48].

7.3 Construct Validity

We manually analyze the correctness of the test-suite adequate patches found by ARJA. Such a manual study is not scientifically sound, although it has been an accepted practice [7], [13] in automated program repair. It may happen that the analysts classify an incorrect patch as correct due to a limited understanding of the buggy program. For example, Martinez et al. [7] claimed that Nopol can synthesize correct patches for bugs C5 and M50, but a recent study [47] indicated that the generated patches are not really correct. To reduce this threat, we carefully rechecked the correctness of the identified correct patches and made the explanation, why we believe they are correct, available online.

ARJA finishes a repair trial for a bug only when the maximum number of generations is reached. So ARJA may finally return multiple test-suite adequate patches (with the same patch size) for a bug. In such a case, we examine the correctness of all the patches obtained, and we deem ARJA to be able to fix this bug correctly if at least one of these patches is identified as correct. We confirm that ARJA outputs both correct and incorrect (i.e., only test-suite adequate) patches for bugs C12, L43 and M22. So a strict criterion for correctness would pose a threat to the validity of the number of correct repairs by ARJA. However, we think it is unrealistic to completely avoid the generation of incorrect but test-suite adequate patches when program repair is just based on a weak test suite. Possibly machine learning techniques [42] can be used to estimate the probability of a patch being correct, but this falls outside the scope of this paper. Further, sometimes it is indeed very difficult to differentiate the incorrect patches from correct ones. For example, Fig. 27 shows a test-suite adequate patch found by ARJA for bug L43. This patch is indeed incorrect but it is very similar to the human-written patch that inserts `next(pos);` before line 5 rather than line 4. Even an experienced human programmer cannot easily recognize it as incorrect without a deep understanding of the program specification. We still think test-suite augmentation is a fundamental solution to the patch overfitting problem.

```
1  // ExtendedMessageFormat.java
2   private StringBuffer appendQuotedString(...) { ...
3  +  next(pos);
4      if (escapingOn && c[start] == QUOTE) {
5       return appendTo == null ? null : appendTo.append(QUOTE);
6      }
7  }
```

Fig. 26. Test-suite adequate patch found by ARJA for bug L43.

Unlike ARJA, jGenProg is terminated once the first test-suite adequate patch is found, and the analysis of correctness only targets this patch. This may lead to a bias toward ARJA when comparing its number of correct fixes with that of jGenProg. jGenProg may still have had the chance to find a correct patch for certain bugs, had it not been terminated immediately. However, we think such bias is

minimal: Except for 5 bugs correctly fixed by both ARJA and jGenProg, jGenProg could not find any patch for 11 out of the remaining 13 bugs that are correctly repaired by ARJA.

8 Related Work

The test-suite based program repair techniques can be roughly divided into two main branches: search-based repair approaches and semantics-based repair approaches. In this section, we first list related studies about these two categories of approaches, then review the research on empirical aspects of test-suite based repair.

8.1 Search-Based Repair Approaches

Search-based repair approaches generally determine a search space that potentially contains correct repairs, and then apply computational search techniques, such as a GA or random search, to navigate the search space, in order to find test-suite adequate patches.

JAFF. Arcuri and Yao [58] proposed the idea of using GP to co-evolve the programs and unit tests, in order to fix a bug automatically. Subsequently, Arcuri [59] developed a research prototype, called JAFF, which models bug fixing as a search problem and uses EAs to solve it. JAFF can only handle a subset of Java and was evaluated on toy programs.

GenProg. GenProg is a prominent GP based program repair system which was developed jointly by several researchers [4], [8], [9], [33]. Le Goues et al. [9] presented the latest GenProg implementation, where the patch representation is used instead of the AST based representation [4], [8], [33] in order to make GenProg scalable to large-scale programs. It was reported in [9] that GenProg can automatically repair 55 out of 105 bugs from 8 open-source programs. Since our study is based on GenProg, a more detailed description was given in Section 2.2.

Around the GenProg framework, a number of related studies have been conducted in the literature. Fast et al. [36] investigated two approaches (i.e., test suite sampling and dynamic predicates) to enhancing fitness functions in GenProg. Schulte et al. [60] applied GenPog to fix bugs in x86 assembly and Java bytecode programs. Le Goues et al. [61] investigated the choices of solution representation and genetic operators for the underlying GP in GenProg. Oliveira et al. [20] presented a low-granularity patch representation and developed several crossover operators associated with this representation. Tan et al. [37] suggested a set of anti-patterns to inhibit GenProg or the other search-based methods from generating nonsensical patches.

Mutation-based repair. Debroy and Wong [62] proposed to combine standard mutation operators (from the mutation testing literature) and fault localization to fix bugs. This method considers each possibly faulty location one by one according to the suspiciousness metric, and mutates the statement at the current location to produce potential fixes.

PAR. Kim et al. [55] proposed PAR, which leverages fix patterns manually learned from human written patches. Similar to GenProg, PAR also implements an evolutionary computing process. But instead of using crossover and mutation operators as in GenProg, PAR uses fix templates derived from common fix patterns to produce new program variants in each generation. Experiments on six Java projects and a user study confirm that the patches generated by PAR are often more meaningful than those by GenProg.

AE. Weimer et al. [63] proposed a deterministic repair algorithm based on program equivalence, called AE. This algorithm uses adaptive search strategies to control the order in which candidate repairs and test cases are considered. Empirical evaluations showed that, AE can reduce the search space by an order of magnitude when compared to GenProg.

RSRepair. Qi et al. [12] presented RSRepair, which replaces the evolutionary search in GenProg with random search. Their experiments on 24 bugs of the GenProg benchmark suite indicate that random search performs more effectively and efficiently than GP in program repair.

SPR. Long and Rinard [64] reported SPR, which adopts a staged program repair strategy to navigate a rich search space of candidate patches efficiently. SPR defines a set of transformation schemas beforehand and uses the target value search or condition synthesis algorithm to determine the parameter values of the selected transformation schema. Experimental results on 69 bugs from 8 open source applications indicate that SPR can generate more correct patches than previous repair systems.

Prophet. Based on SPR, Long and Rinard [42] further designed Prophet, a repair system using a probabilistic model to rank candidate patches in the search space of SPR. Given a training set of successful human patches, Prophet learns model parameters via maximum likelihood estimation. Experimental results indicate that a learned model in Prophet can significantly improve its ability to generate correct patches.

HistoricalFix. Le et al. [45] introduced a repair method which evolves patches based on bug fix patterns mined from the history of many projects. This method uses 12 kinds of existing mutation operators to generate candidate patches and determines the fitness of a patch by assessing its similarity to the mined bug-fixing patches. Experimental results on 90 bugs from Defects4J show that the proposed method can produce good-quality fixes for more bugs compared to GenProg and PAR.

ACS. Xiong et al. [46] reported ACS, a repair system targeting `if` condition bugs. ACS decomposes the condition synthesis into two steps: variable selection and predicate selection. Based on the decomposition, it uses dependency-based ordering along with the information of javadoc comments to rank the variables, and uses predicate mining to rank predicates. With a synthesized condition, ACS leverages three fix templates to generate a patch. Experiments show that ACS can successfully repair 18 bugs from four projects of Defects4J.

Genesis. Long et al. [65] presented a repair system, called Genesis, which can automatically infer code transforms and search spaces for patch generation. Genesis was tested on two classes of errors (i.e., null pointer errors and out of bounds errors) in real-world Java programs.

Discussion of Differences. The major differences between ARJA and GenProg were discussed in Section 2.4. To explore the repair search space, PAR and HistoricalFix basically employ the evolutionary search of GenProg, RSRepair uses random search, and the other approaches listed above es-

0098-5589 (c) 2018 IEEE. Personal use is permitted, but republication/redistribution requires IEEE permission. See http://www.ieee.org/publications_standards/publications/rights/index.html for more information.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

sentially use enumerative search. So in terms of the search algorithm, the novel multi-objective GP with rule-based search space reduction makes ARJA distinctly different from these repair approaches. PAR, SPR and Prophet mutate the buggy program according to predefined fix templates while ARJA does this mainly by rearranging existing statements. So PAR, SPR and Prophet may be better at fixing some common bugs (e.g., null pointer error) while ARJA may have an advantage in handling bug fixes that require more complex program transformations. ACS and Genesis only target specific kinds of bugs while ARJA is a generic approach. Moreover, to speed up the patch validation, AE and RSRepair use test case prioritization techniques. However such techniques cannot be used in ARJA since GP requires fitness evaluation. ARJA conducts lightweight impact analysis to reduce the test suite instead of prioritizing test cases.

8.2 Semantics-Based Repair Approaches

Typically, the semantics-based repair approaches infer semantic constraints from the given test cases, and then generate the test-suite adequate patch through solving the resulting constraint satisfaction problem, particularly the SMT problem.

SemFix. Nguyen et al. [15] proposed SemFix, a pioneering tool for semantic-based program repair. SemFix first employs statistical fault localization to identify likely-buggy statements. Then, for each identified statement, it generates repair constraints through symbolic execution of the given test suite and solves the resulting constraints by an SMT solver. SemFix targets faulty locations that are either a right hand side of an assignment or a branch predicate, and was compared to GP based methods on programs with seeded as well as real bugs.

SearchRepair. Ke et al. [16] developed a repair method based on semantic code search, called SearchRepair. This method encodes a database of human-written code fragments as SMT constraints on the input-output behavior and searches the database for potential fixes with an input-output specification. Experiments on small C programs written by students showed that SearchRepair can generate higher-quality repairs than GenProg, AE and RSRepair.

DirectFix. Mechtaev et al. [66] implemented a prototype system, called DirectFix, for automatic program repair. To consider the simplicity of repairs, DirectFix integrates fault localization and patch generation into a single step by leveraging partial maximum SMT constraint solving and component-based program synthesis. Experimental comparison indicates that the patches found by DirectFix are simpler and safer than those by SemFix.

QLOSE. D'Antoni et al. [67] formulated the quantitative program repair problem, where the optimal repair is obtained by minimizing an objective function combing several syntactic and semantic distances to the buggy program. The problem is an instance of maximum SMT problem and is solved by an existing program synthesizer. The technique was implemented in a prototype tool called QLOSE and was evaluated on programs taken from educational tools.

Angelix, JFix. Mechtaev et al. [68] presented Angelix, a semantic-based repair method that is more scalable than SemFix and DirectFix. The scalability of Angelix attributes to the new lightweight repair constraint (called an angelic forest), which is independent of the size of the program under repair. Experimental studies on the GenProg benchmark indicate that Angelix has the ability to fix bugs from large-scale software and multi-location bugs. Angelix was originally designed for C programs. Recently, Le et al. [69] developed JFix which is an extension of Angelix for Java.

Nopol. Xuan et al. [35] proposed an approach, called Nopol, for automatic repair of buggy conditional statements in Java programs. Nopol employs angelic fix localization to identify potential fix locations and expected values of `if` conditions. For each identified location, it encodes the test execution traces as a SMT problem and converts the solution to this SMT into a patch for the buggy program. Nopol was evaluated on 22 bugs in real-world programs.

S3. Le et al. [70] presented S3 which uses the methodology of programming by examples to synthesize high-quality patches. S3 was evaluated on 52 bugs in small programs and 100 bugs in real-world large programs, and experimental results show that it can generate more high-quality repairs than several existing semantic-based repair methods.

Discussion of Differences. SearchRepair leverages code from an external code base while ARJA uses existing statements in the buggy program or further leverages their syntactic patterns to create new code. Similar to DirectFix, ARJA also aims to look for simpler patches. DirectFix takes into account the simplicity of the repair via partial maximum SMT constraint solving, while ARJA considers this by explicitly minimizing the patch size in evolutionary multi-objective optimization. Angelix and S3 generate multi-location repairs by using the angelic forest while ARJA achieves it by leveraging the expressive power of GP. Moreover, SemFix, DirectFix, Angelix, Nopol and S3 mainly focus on synthesizing conditions to fix a bug while ARJA is more general.

8.3 Empirical Aspects of Test-Suite Based Repair

Besides proposing new program repair methods, there is another line of research that focuses on the empirical aspects of test-suite based repair.

Patch maintainability. Fry et al. [71] presented a human study of patch maintainability involving 150 participants and 32 real-world defects. Their results indicate that machine-generated patches are slightly less maintainable than human-written ones. Tao et al. [72] investigated an application scenario of automatic program repair where the auto-generated patches are used to aid the debugging process by humans.

Redundancy assumption. Martinez et al. [17] investigated all commits of 6 open-source Java projects experimentally, and found that a large portion of commits can be composed of what has already existed in previous commits, thereby validating the fundamental redundancy assumption of GenProg. In the same year, Barr et al. [18] inquired whether the redundancy assumption (or plastic surgery hypothesis) holds by examining 15,723 commits from 12 large Java projects. Their results show that 43% changes can be reconstituted from existing code, thus promising success to the repair methods that search for fix ingredients in the buggy program considered.

This article has been accepted for publication in a future issue of this journal, but has not been fully edited. Content may change prior to final publication. Citation information: DOI 10.1109/TSE.2018.2874648, IEEE Transactions on Software Engineering

Patch overfitting. Qi et al. [13] analyzed the patches reported by three existing patch generation systems (i.e., GenProg, RSRepair, and AE), and found that most of these are not correct and are equivalent to a single functionality deletion, due to either the use of weak proxies or weak test suites. Based on this observation, they presented Kali which generates patches only by deleting functionality. Their experiments show that Kali can find at least as many plausible patches than three prior systems on the GenProg benchmark. Smith et al. [53] conducted a controlled empirical study of GenProg and RSRepair on the IntroClass benchmark. By using two test suites for each program (one for patch generation and another for evaluation), their experiments identified the circumstances under which patch overfitting happens. Long and Rinard. [73] analyzed the search spaces for patch generation systems. Their analysis indicates that correct patches occur sparsely within the search spaces and that plausible patches are relatively abundant compared to correct patches. They suggest using information other than the test suite to isolate correct patches. Yu et al. [47] investigated the feasibility and effectiveness of test case generation in addressing the overfitting problem. Their results indicate that test case generation is ineffective at promoting the generation of correct patches, thus calling for research on test case generation techniques tailored to program repair systems. Xin et al. [48] proposed a tool named DiffTGen, which could identify overfitting patches through test case generation. They also showed that a repair method configured with DiffTGen could avoid obtaining overfitting patches and potentially generate correct ones. Yang et al. [54] presented an overfitting patch detection framework which can filter out overfitting patches by enhancing existing test cases.

Analysis of real-world bug fixes. Martinez and Monperrus [38] proposed to mine repair actions from software repositories. Based on a fine-grain AST differencing tool, their work analyzed 62,179 versioning transactions extracted from 14 repositories of open-source Java software, in order to obtain the probability distributions over different repair actions. It was expected that such distributions can guide the search of repair methods. Zhong and Su [74] conducted a large-scale empirical investigation on over 9,000 bug fixes from 6 popular Java projects, then distilled several findings and insights that can help improve state-of-the-art repair methods. Soto et al. [75] presented a large-scale empirical study of bug fix commits in Java projects. Their work provided several insights about broad characteristics, fix patterns, and statement-level mutations in real-world bug fixes, motivating additional study of repair for Java.

Performance evaluation. Kong et al. [76] compared four program repair techniques on 153 bugs from 9 small to medium sized programs, and investigated the impacts of different programs and test suites on effectiveness and efficiency of the techniques in comparison. Martinez et al. [7] conducted a large-scale empirical evaluation of program repair methods on 224 bugs in Defects4J. Their experimental results showed that three considered methods (i.e., GenProg, Kali, and Nopol) can generate test-adequate patches for 47 bugs, among which 9 bugs were confirmed to be repaired correctly by manual. Le et al. [77] presented an empirical comparison of different synthesis engines for semantics-based repair approaches on IntroClass benchmark. Durieux et al. [78] reported the test-adequate patches obtained by Nopol on the bugs of Defects4J version 1.1.0.

Influence of fault localization. Qi et al. [79] evaluated the effectiveness of 15 popular fault localization techniques when plugged into GenPog. Their work claims that automated fault localization techniques need to be studied from the viewpoint of fully automated debugging. Assiri and Bieman [80] experimentally evaluated the impact of 10 fault location techniques on the effectiveness, performance, and repair correctness of a brute-force repair method. Wen et al. [81] conducted controlled experiments using the Defects4J dataset to investigate the influence of the fault space on a typical search-based repair approach (i.e., GenProg).

Datasets. Just et al. [19] presented Defects4J which is a bug database containing 357 real bugs from 5 real-world open-source Java projects. Le Goues et al. [82] designed two datasets (i.e., ManyBugs and IntroClass), which consist of 1,183 bugs in 15 C programs and support the comparative evaluation of repair algorithms for various of experimental questions. Tan et al. [83] presented a dataset, called Codeflaws, where all 3,902 defects contained from 7,436 C programs are classified into 39 defect classes. Berlin [84] collected a dataset called DBGBench, which consists of 27 real bugs in widely-used C programs and can serve as reality check for debugging and repair approaches.

9 Conclusion and Future Work

In this paper, we have proposed ARJA, a new GP based program repair approach for Java. Specifically, we present a lower-granularity patch representation which properly decouples the search subspaces of likely-buggy locations, operation types and ingredient statements, thereby enabling GP to traverse the search space more effectively. Based on this new representation, we propose to view automated program repair as a multi-objective optimization problem of minimizing the weighted failure rate and patch size simultaneously, and then use a multi-objective GA (i.e., NSGA-II) to search for simpler repairs. To speed up the fitness evaluation of GP, a test filtering procedure is used to ignore unrelated tests. To reduce the search space, we design three types of rules that are seamlessly integrated into three different phases (i.e., operation initialization, ingredient screening and solution decoding) of ARJA. In addition, we present a type matching strategy that can exploit the syntactic patterns of the statements that are out of scope at the destination so as to invent some new ingredient statements that are potentially useful. The type matching strategy can be optionally integrated into ARJA.

We conduct a large-scale experimental study on both seeded bugs and real-world bugs. The evaluation on seeded bugs clearly demonstrates the necessity and effectiveness of multi-objective GP used in ARJA, and also illustrates the strength of the type matching strategy. Furthermore, we evaluate ARJA and its three variants using type matching on 224 real-world bugs from Defects4J, in comparison with several state-of-the-art repair approaches. The comparison results show that ARJA can generate a test-suite adequate patch for the highest number (i.e., 59) of real bugs, as opposed to only 27 by jGenProg and 35 by Nopol. The three

ARJA variants can fix some bugs that cannot be fixed by ARJA, showing the potential of type matching on real-world bugs. Manual analysis confirms that ARJA can correctly fix 18 bugs at least in Defects4J, as opposed to 5 by jGenProg. To our knowledge, there are 7 among the 18 bugs that are repaired automatically and correctly for the first time. Another highlight is that ARJA can correctly repair several multi-location bugs that are widely recognized as hard to be repaired. Our study strongly suggests that the power of GP for program repair was far from being fully exploited in the past, and that GP can be expected to perform much better on this important and challenging task.

Although ARJA shows promising performance, we realize that the number of bugs correctly fixed by ARJA is still quite low. Currently, practitioners cannot rely on a single tool when repairing bugs. It may be a good practice to run several advanced tools in parallel so as to increase the chance for fixing a bug.

ARJA is publicly available at GitHub to facilitate further reproducible research on automated Java program repair: http://github.com/yyxhdy/arja.

In the future, we plan to incorporate a number of repair templates [55] into our ARJA framework so as to further enhance its performance on real-world bugs. Moreover, considering the mutational robustness [85] in software, we would like to combine the infrastructure of ARJA and advanced many-objective GAs [86], [87] to improve non-functional properties [27], [29] of Java software.

ACKNOWLEDGMENT

Discussions with B. Alexander, S. Forrest, M. Harman, W.B. Langdon, C. Le Goues, A. Roychoudhury and D.R. White are gratefully acknowledged. We would like to thank three anonymous reviewers for their insightful comments on an earlier version of this paper.

Yuan Yuan is currently a Postdoctoral Research Fellow with the Department of Computer Science and Engineering, Michigan State University, USA. He received the Ph.D. degree from the Department of Computer Science and Technology, Tsinghua University, Beijing, China, in 2015. From 2014 to 2015, he was a visiting Ph.D. student with the Centre of Excellence for Research in Computational Intelligence and Applications, University of Birmingham, U.K. He worked as a Research Fellow at the School of Computer Science and Engineering, Nanyang Technological University, Singapore, from 2015 to 2016. His research interests include evolutionary computation, machine learning, and search-based software engineering.

Wolfgang Banzhaf is the John R. Koza Chair for Genetic Programming in the Department of Computer Science and Engineering at Michigan State University, USA. Previously, he was University Research Professor in the Department of Computer Science of Memorial University of Newfoundland, Canada, where he served as head of department 2003–2009 and 2012–2016. His research interests are in the field of bio-inspired computing, notably evolutionary computation and complex adaptive systems. Studies of self-organization and the field of Artificial Life are also of very much interest to him. Recently he has become more involved with network research as it applies to natural and man-made systems.
